Fabrication and Characterization of a Plasmonic Biosensor Using Non-Spherical Metal Nanoparticles

by

Bong-Su Jung, B.S.; M.S.E.

Dissertation

Presented to the Faculty of the Graduate School of

The University of Texas at Austin

in Partial Fulfillment

of the Requirements

for the Degree of

Doctor of Philosophy

The University of Texas at Austin

December 2007

Dedication

To my beloved family:
Father, mother, my sisters,
and my grandmother in heaven.

Acknowledgements

I would like to sincerely thank my parents, Woon-choong Jung, Eun-sook Lee and all my loving sisters, Su-Ah, Hyun-Ah, Jin-Ah, and Eun-Hye for their cares and prayers for me.

I am very grateful for having had such a wonderful supervisor Dr. Wolfgang Frey who had guided me through my studies. Whenever I experienced trouble in my research, he always provided me with solid academic advice.

I must also thank so many of my peers in my lab, John Slater, Ted Gaubert, and Ruben Morones for their encouragement, support and friendship. I'd like to thank Heidi Fagerlund, the graduate coordinator in BME, UT Austin. She is not only my graduate coordinator, but also has been such a good friend to me. We have enjoyed talks on many topics, including different cultural ideas and scientific issues. I must also thank most of the staff at BME, UT Austin: Vicki Stratton, Ann Armstrong, Cheryl Sandoval, Joni Burks, Jim Pollard, Cindy Zimmerman, and Chris Cooper. They have been so helpful over the past few years.

I would like to express my sincere gratitude to the Center for Nano and Molecular Science and Technology at UT Austin for their facilities and Welch foundation for the financial support they provided.

Above all, I would thank God for giving me health, strength, encouragement, intuition and wisdom. My studies have always been a wonderful blessing right from the very beginning until now.

Fabrication and Characterization of a Plasmonic Biosensor Using Non-Spherical Metal Nanoparticles

Publication No. _____

Bong-Su Jung, Ph.D.

The University of Texas at Austin, 2007

Supervisor: Wolfgang Frey

Label-free detection techniques have an important role in many applications, such as situations where few molecules – rather than low molarity – need to be detected, such as in single-cell screening. While surface plasmon resonance (SPR) scattering from metal nanoparticles has been shown to achieve significantly higher sensitivity in gene arrays, such an approach has not been demonstrated for protein arrays. SPR-based sensors could either use simple absorption measurement in a UV-Vis spectrometer or possibly surface-enhanced Raman spectroscopy as the detection mechanism for molecules of interest.

However, non-spherical particles are needed to achieve high sensitivity and field enhancement that is a requirement in both techniques, but these shapes are not easy to produce reproducibly and preserve for extended periods of time. Here I present a carbon-based template-stripping method combined with nanosphere lithography (NSL). This fabrication allows to preserve the sharp features in atomically flat surfaces which are a composite of a non-spherical metal nano-particle (gold or silver) and a transparent embedding material such as glass. The stripping process is residue-free due to the

introduction of a sacrificial carbon layer. The nanometer scale flat surface of our template stripping process is also precious for general protein absorption studies, because an inherent material contrast can resolve binding of layers on the 2 nm scale.

These nanocomposite surfaces also allow us to tailor well-defined SPR extinction peaks with locations in the visible or infrared spectrum depending on the metal and the particle size and the degree of non-symmetry. As the particle thickness is reduced and the particle bisector length is increased, the peak position of the resonance shifts to the red. Not only the peak position shifts, but also the sensitivity to environmental changes increases. Therefore, the peak position of the resonance spectrum is dependent on the dielectric environmental changes of each particle, and the particle geometries. The resulting silver or gold nanoparticles in the surface of a glass slide are capable of detecting thiol surface modification, and biotin-streptavidin protein binding events. Since each gold or silver particle principally acts as an independent sensor, on the order of a few thousand molecules can be detected, and the sensor can be miniaturized without loss of sensitivity.

UNSL-Au metal nanoparticle (MNP) sensors achieve the sensitivity of close to 300 nm/RIU which is higher than any other report of localized surface plasmon resonance (LSPR) sensors except gold nanocrescents. Finite-difference-time-domain (FDTD) and finite-element-method (FEM) numerical calculations display the influence of the sharp features on the resonance peak position. The maximum near-field intensity is dependent on the polarization direction, the sharpness of the feature, and the near-field confinement from the substrate. 3D FDTD simulation shows the local refractive index sensitivity of the gold truncated tetrahedron, which is in agreement with our experimental result. Both experimental and numerical calculations show that each particle can act as its own sensor.

Table of Contents

List of Figures	xi
Chapter 1: Introduction	1
1.1 Background and motivation	1
1.1.1 Proteomics	1
1.1.2 Localized surface plasmon resonance as a label-free detection method	2
1.2 Achievements of specific aims	6
1.3 Dissertation overview	9
1.4 References	10
Chapter 2: Fundamental Theory	14
2.1 Principle of localized surface plasmon resonance	14
2.2.1 Spherical metal particles	15
2.2.2 Mie theory for spherical particles	19
2.2.3 Various computational methods for Non-spherical MNPs	22
2.2.4 Sensitivity of MNP plasmonic sensor to the dielectric environment	29
2.2.5 References	32
Chapter 3: Fabrication of carbon based template-stripping method for large scale nanopatterned atomic scale flat surfaces	36
3.1 Introduction	36
3.2 Experimental Methods	39
3.3 Results and Discussion	42
3.3.1 Sample fabrication and characterization	42
3.3.2 Selective functionalization of the nanopattern	49
3.4 Conclusions	51
3.5 References	52

Chapter 4: Plasmonic optical sensor: Sensitivity of the bulk and local refractive index change and geometrical influences	56
4.1 Introduction.....	56
4.2 Experimental Methods	57
4.3 Results and Discussion	59
4.3.1 The bulk plasma and LSPR Absorption Spectroscopy	59
4.3.2 Role of the Geometry on the Properties of LSPR sensitivity in UNSL samples.....	63
4.3.3 The bulk refractive index sensitivity of LSPR in UNSL samples.....	65
4.3.4 The local refractive index sensitivity of LSPR in UNSL samples.....	75
4.3.5 Comparison of the refractive index sensitivity in unit sensing area in NSL and UNSL.....	81
4.4 Conclusions.....	85
4.5 References.....	87
Chapter 5: Computational modeling for near-field and far-field investigations of non-spherical triangular particles	91
5.1 Introduction.....	91
5.2 Theoretical methods.....	92
5.3 Results and Discussion	97
5.3.1 Rayleigh scattering for a dielectric sphere.....	97
5.3.2 Far-field calculation for a free-standing truncated tetrahedron gold MNP in air.....	98
5.3.3 Near-field intensity distribution near the sharp features of non-spherical MNPs.....	100
5.3.4 Substrate influence of the near-field intensity of non-spherical MNPs	103
5.4 Conclusions.....	110
5.5 References.....	110

Chapter 1: Introduction

1.1 BACKGROUND AND MOTIVATION

1.1.1 Proteomics

With the successful completion of the human DNA map, researchers discussed that merely having a complete sequence of genomes is not enough to reveal biological functions [1]. The reason is that there is not necessarily a direct relationship between genes and the amount and the activity of the cellular protein content. The DNA sequence is translated into a corresponding mRNA sequence which is used by the ribosome to synthesize an amino acid sequence. However, a gene can undergo different splicings during transcription, and a protein can also undergo posttranslational modifications which result in various active forms of a protein. Discrepancies between genetic expression, i.e. the amount of mRNA, and the amount of active proteins also occur due to differences in the rate of degradation of proteins and gene sequences [2]. Therefore genomics has a fundamental limitation when elucidating functions of the gene products.

Proteomics is complementary to genomics, in that, it provides tools for the investigation of proteins, i.e. the gene products [3]. cDNA, derived from mRNA by reverse transcriptase, is used for transcription and expression analysis in the form of DNA arrays. In analogy to the very successful cDNA arrays, proteomic arrays promise to be a tool for detecting, comparing and measuring the presence of biomolecules, protein activity, binding kinetics and local concentration, which are all major parts of proteomic analysis of cellular function.

Fluorescent marker techniques such as ELISA (Enzyme-Linked ImmunoSorbent Assay) or GFP (green fluorescent protein) are currently popular methods in protein

detection. However, any fluorescent labeling technique has problems such as photo-bleaching, and concentration dependence of the fluorescence. Fluorescence methods also require complicated and labor intensive processing to attach the label. In one very powerful technique, GFP is fused to the target protein and co-expressed in the cell. However, these fusions are often transient and this method cannot be applied in cases where transfection is not applicable. In order to systematically analyze the protein, labeling techniques have to be complemented by powerful non-labeling techniques.

1.1.2 Localized surface plasmon resonance as a label-free detection method

Noble metal nanoparticles (MNPs) have unique optical, chemical and electrical properties. MNPs such as silver or gold exhibit a strong absorption band in the visible spectrum that is not found for the bulk metal [4]. The absorption is induced when the frequency of the incident light is resonant with the collective oscillations of the conduction electrons in the MNP. Since this excitation is localized, it is called localized surface plasmon resonance (LSPR) [5, 6].

Noble metals, especially gold are biocompatible, relatively easy to synthesize and chemically functionalize. Gold MNP surface modification for protein immobilization is straight forward, using thiol chemistry. Gold has been conjugated with DNA [7, 8], antibodies [9] and other biomolecular ligands [10]. Even more, LSPR of gold or silver MNPs is sensitive to size [4, 5, 11, 12], and shape [4, 5, 13], and changes in the environment [14, 15]. Due to these unique chemical, electrical, and optical properties, spherical gold MNPs, which can be synthesized by solution chemistry have been attractive as sensors [9, 16]. Sensors have been fabricated using colloidal gold MNPs immobilized on glass [17, 18] or in solution for antibody- antigen binding kinetics [9]. Gold-labeled ss-DNA strands produce a different absorption spectrum depending on whether the DNA strands are hybridized or were de-hybridized [7]. Compared to

fluorescent labels, such as Cy3 and Cy5, this results in a far more sensitive detection of DNA hybridization, and is based on the relative distance of the absorption spectrum of two gold MNPs [19, 20]. The enhanced field at LSPR MNPs allows for surface-enhanced Raman scattering (SERS) spectroscopy to be used, a technique that potentially could eliminate the use of capturing agents. For instance, gold MNPs were used as a probe to detect multiple oligonucleotide targets with SERS and different Raman dyes [21]. Finally, colloidal gold nanoparticles are used as optical contrast agents for real-time, non-bleaching *in vivo* imaging for cancer detection [22] and thermal ablation sources using the optically induced heating of nanoshell structures for cancer imaging and therapy [23, 24]

LSPR is very suitable for nanoscale detection, because a single MNP can act as a sensor [13, 25-29] (Figure 1.1). For instance, a layer of 1-hexadecanethiol (1-HDT) or about 60,000 molecules (~100 zeptomoles), can easily be detected. Most of these colloidal MNP sensors reach picomolar sensitivity which can detect specific antibodies and a single epitope interaction on the ligand [9, 18]. Although the sensitivity of a sensor is often determined by the equilibrium constant K_a of the affinity ligand, LSPR sensors can measure very small absolute quantities of ligands in a very small sample volume.

The sensitivity of a LSPR sensor can be enhanced by the presence of higher fields around the edges of a MNP, and non-spherical MNP sensors [30, 31], which have been shown to have highly enhanced fields at tips and edges [32-34], are very sensitive to changes in the dielectric constant of the environment. However, sharp features like corners and edges often cannot be preserved during chemical modification. Thus, thermal and solvent annealing have to be performed in order to get grounded sharp features and make the sensor more reliable and reproducible [34, 35]. This process significantly reduces electric fields and therefore sensitivities to the environmental changes

(Figure 1.1 A). Thus, in order to preserve the field enhancement and the higher sensitivity, the sharp corners and edges of non-spherical NPs have to be preserved (Figure 1.1 B).

Figure 1.1: Illustration of a single LSPR sensor. (a) a NSL-fabricated LSPR sensor. The LSPR is not reproducible and has reduced sensitivity due to rounded sharp corners of the truncated tetrahedron. Dotted line shows irreproducibility (b) an UNSL-fabricated LSPR sensor. The truncated tetrahedron is partially embedded into a substrate to preserve the sharp corners.

Not only can single MNPs act as individual LSPR sensors, but they can, either individually or in small groups, be integrated into a sensor array which then requires minimal amounts of sample and ligand and could be valuable in proteomics research. Site-selective capture mechanism such as an affinity ligand binding is the most common technique in protein arrays [36-38]. To achieve high-throughput in protein detection, MNP LSPR sensor arrays require multiple areas of selective patterning and protein immobilization, which define areas that represent a single element in the array. Additionally, the sensor surface should prevent lateral spreading and contamination during the spotting process (Figure 1.2).

This sensor can be measured with UV-Vis spectrometry, dark-field scattering, and with optical wave guides.

Figure 1.2: Illustration of an array type MNP LSPR sensor. This array type sensor allows high-throughput protein detection by target protein immobilization and positioning. Site-selective proteins are captured by immobilized ligands in multiple protein arrays.

In order to fabricate array types of non-spherical MNPs many lithography techniques, such as electron-beam lithography or nanosphere lithography (NSL) have been used. However, these methods are either very slow or the particle shape, such as the triangle tips of the NPs, degrade easily. Sensors also have been demonstrated using solution-based synthesis of non-spherical MNPs such as cubes [30] and triangles [31]. As mentioned earlier, although these particles can reach high sensitivities, they also suffer from rounding of their edges. Ultraflat nanosphere lithography (UNSL), which combines NSL and carbon-based template-stripping method in this thesis not only preserves sharp features, but also changes the MNP shape to enhance the sensitivity with varying non-symmetrical geometries.

In this thesis we try to understand the electromagnetic field interactions of partially embedded non-spherical MNPs of different geometrical parameters in various

environments, and perform numerical calculations, such as Finite-Difference-Time-Domain (FDTD) and Finite-Element-Method (FEM).

1.2 ACHIEVEMENTS OF SPECIFIC AIMS

It was proposed to develop a highly sensitive label-free non-spherical MNP sensor for detecting environmental changes and biomolecular binding events without losing any sharpness features. This technique should be also a simple, fast, parallel and cheap process to produce a large number of nanostructures that can be used for an array-type sensor. Therefore, the specific aims in this dissertation were to (i) develop a sensor that preserves the sharpness of the MNPs by partially embedding the particles in a substrate, so that sharp corners and edges are stabilized while still exposed to the chemical modification in order to achieve high sensitivity. (ii) optimize the sensitivity of highly elongated non-spherical MNPs, and determine most sensitive array parameters (iii) explore other implementations of sensors, such as extraordinary optical transmission of partially embedded MNPs, or coupled LSPR and propagating SPR spectroscopy, for use as a label free sensor, (iv) and model the near- and far-fields around the MNPs with numerical simulations.

1: Study of the sensitivity of non-spherical and metal nanoparticles with preserved shape to changes in the dielectric environment.

It was suggested to investigate which parameters of the non-spherical geometries play a role in the sensitivity of the MNP plasmonic sensor. Conventional NSL and ultraflat nanosphere lithography (UNSL) have some limitations to study this sensitivity. It has been known that NSL-fabricated MNPs are easily rounded and causes reliability issues. The sample surface from conventional UNSL-fabricated MNPs are often not homogeneous due to mica shards which remained on the surface. The mica shards (which change the dielectric constant of the ambient medium near the MNPs) induce

irreproducible and convoluted resonance responses in the experiments. It was very difficult to remove the very thin residues of mica from the UNSL surface, because the binding force between the mica substrate and the composite nanopatterned surface can be very strong. Therefore, new a fabrication technique had to be designed to get a residue-free and homogeneous nanopatterned surface to investigate the sensitivity of the MNP sensor. It is then possible to create homogenously distributed tetrahedron gold MNPs over centimeter scale using a carbon-based template stripping dry etching technique.

With this new fabrication technique, some important geometrical parameters that change the sensor sensitivity were found. The thickness which is the side of the truncated tetrahedron and the bisector of the triangular surface in the non-spherical MNPs were varied to study the sensitivity response. These parameters influence the peak position of the resonance. Thinner and longer (bisector) particles induce a red-shift of the resonance. Not only the peak position, but also the sensitivity is influenced with those geometry parameters. The sensitivity is significantly increased by increasing the bisector length and reducing the particle thickness, especially if the particle becomes very thin. Tailoring LSPR, we achieved close to 300 nm/ RIU in the bulk refractive index sensitivity with a 20 nm thick and 117 nm long particle.

2: Development and characterization of the surface plasmon-based sensor into an array molecular sensor for protein detection.

The capability to detect proteins is one of the fundamental requirements for a plasmonic sensor in biomedical applications. Therefore, using the sensor to detect small changes in the near-field environment due to adsorbates, such as thiol molecules on the nanopatterned surface or affinity ligand binding like biotin-streptavidin, was proposed. The newly fabricated gold MNP sensor detects the local refractive index changes. With the optimized gold UNSL sensor, it was possible to detect hexadecanethiol (HDT)

binding with 30 nm of red peak shift and 100 nM of streptavidin binding on the biotinylated layer on the sensor. The gold MNP UNSL sensor detected biotin binding with 29 nm of red shift and streptavidin binding on the biotin layer with 7 nm of the red shift in air.

Having atomically flat surfaces, selectively grouping and separately functionalizing MNPs to achieve an array of protein ligand patterns is possible, so that this array of sensors can be applied in proteomics.

3: Explore other sensor implementations, such as extraordinary optical transmission on non-perforated nanostructures, or coupling LSPR and propagating SPR spectroscopy.

A plane wave cannot propagate through an aperture with a size smaller than half the wavelength of the light, and the transmission signal is very weak. Contradictory to this well-known effect, extraordinary transmission was found in subwavelength holes surrounded by a corrugated surface or an array of holes in an opaque film of a metal that supports propagating surface plasmons [28, 39]. It was hypothesized that localized surface plasmon resonance also supports extraordinary transmission. To examine this theory, non-surface plasmon supporting opaque films were fabricated. These films which were made with Al or Ag layers with embedded gold and silver MNPs, without any holes were measured at visible wavelengths. Although changes in the transmission were found, no sensitivity to the environment were detected (these results are not shown in this dissertation).

4: Modeling of the local electric fields in the vicinity of the particle and of the total scattering and absorption cross sections.

Understanding the plasmonic resonances of non-spherical MNPs using numerical simulations is an essential step in the study of LSPR, and enables us to compare and

understand the experimental results. Therefore, it was proposed to use numerical tools such as FDTD in this research. Therefore, FEMLAB 3.3a® as FEM and XFDTD® as FDTD were used in the numerical calculation in this dissertation. 2D in plane and cross-sectional simulations were performed with FEMLAB 3.3a® and 3D FDTD simulation performed with XFDTD®. The numerical calculations show that there is geometrical influence at the sharp features and a substrate influence in the near-field. The maximum near-field intensity always exists along the polarization direction, and is also influenced by the substrate. The near-field intensity directly affects the far-field intensity, which is measured experimentally by UV-Vis spectroscopy. The wavelength at which the maximum near-field intensity is found is also the wavelength of the resonance peak position in the far-field analysis. Understanding the plasmonic resonance with numerical calculation also opens up future research to design different types of sensors and supports pioneering experiments in plasmonics.

1.3 DISSERTATION OVERVIEW

The goals of this dissertation are to fabricate and preserve non-spherical features especially sharp corners and edges using a new nanofabrication technique, and to create a label-free plasmonic sensor and characterize and optimize the sensitivity of the sensor. To understand the plasmonic behavior induced by the non-spherical particle features, numerical computation was performed by Finite-Element-Method (FEM) and Finite-Difference-Time-Domain (FDTD) and compared with the experimental results in this dissertation

Chapter 2 describes the fundamental theory of localized surface plasmon resonance (LSPR) for spherical metal nanoparticles (MNPs) and non-spherical MNPs. The fundamental algorithms of FEM and FDTD are explained in Chapter 5. Chapter 2

also explores the study of the sensitivity in different types of non-spherical MNPs from other groups.

Chapter 3 introduces a new fabrication method to create and preserve non-spherical MNPs (truncated tetrahedron) in a transparent substrate. By using a carbon sacrificial layer in the fabrication step the quality of the MNPs is improved .

Chapter 4 analyzes the experimental results of LSPR properties from non-spherical gold and silver MNPs fabricated as described in Chapter 3. The sensor sensitivity to the bulk and the local refractive index changes is characterized and compared with the non-spherical MNPs from the conventional nanosphere lithography (NSL) technique.

Chapter 5 compares some of the experimental results from Chapter 4 with computational modeling results. FEMLAB 3.3a® as a FEM tool and XFDTD® as a FDTD tool are used to compute the numerical calculation. These numerical tools support the experimental results in Chapter 4 and provides valuable information about LSPR properties from the sharp features in the non-spherical MNPs.

Chapter 6 summarizes the results and indicates future work.

Chapter 2: Fundamental Theory

2.1 PRINCIPLE OF LOCALIZED SURFACE PLASMON RESONANCE

Conventional propagating SPR spectroscopy achieves sub-picomolar detection levels [1], but its application is not useful in high throughput screening [2]. When very small sample volumes have to be processed, the sensing area has to be limited to sizes in the range of (or smaller than) the decay distance of the surface plasmon. These limitations can be overcome with colloidal nano-particle plasmon resonance which is often called localized SPR (LSPR). LSPR is the localized collective excitation of electrons (or resonance electron oscillation) in the conduction band in metal nanoparticles (MNPs) by light radiation. The use of colloidal type gold or silver particle surface plasmon resonance sensors is an emerging non-labeling method [3]. A change of refractive index close to the surface of the MNP induces a shift in the resonance absorption wavelength of the LSPR. The magnitude of this shift, the sensitivity of the sensor, depends on the metal particle size and shape [4]. When MNPs are close to a substrate or embedded in the substrate, the sensitivity is also influenced by the properties of the substrate [5]. LSPR promises to be of great usefulness for proteomics, offering relatively high sensitivity, but more importantly, the ability to detect very low numbers of molecules – up to zeptomoles ($1\text{zM}=10^{-21}$ mols) – for small sample volumes. In order to understand colloidal surface plasmon resonance or localized SPR, it is important to understand light scattering on a particle smaller or of the size of the wavelength of the incoming light.

2.2.1 Spherical metal particles

When a small spherical MNP is illuminated by light of a wavelength much larger than the particle size, the oscillation of the incoming electric field of the light causes the conduction electrons of the metal to oscillate coherently (Figure 2.2.1). The lowest order of the excitation is called dipole particle plasmon resonance or quasi-static approximation, as the particle becomes polarized homogeneously by a time-varying, but otherwise constant electromagnetic field.

Figure 2.2.1: Illustration of excited particle plasmon oscillation by an electromagnetic field.

The oscillating dipole polarization P in a metallic sphere is described by [6]

$$P = \frac{3(\varepsilon - 1)}{4\pi(\varepsilon + 2) - (\varepsilon - 1)(k^2 4\pi a^2 + i \frac{2}{3} k^3 4\pi a^3)} E_o \quad (2.2.1)$$

where a = particle radius, $k = \frac{2\pi}{\lambda} n$ = wave vector, $\varepsilon = \varepsilon_1 + i\varepsilon_2$ is the complex dielectric constant of metal relative to the environment, and E_o is the externally applied

field. This equation shows that external dielectrics change the dipole polarization through k and ε . Thus, the refractive index sensitivities can be understood by the extinction peak position changes of the plasmon resonance.

The first term of the denominator of Equation (2.2.1) indicates stationary polarization and presents the Clausius-Mosotti result for the polarization of a sphere. The second and third term are higher order terms in ka , which relate the particle size to the wavelength and account for the finite size of a particle. The second order term of the denominator, which depends on $k^2 a^2$, expresses dynamic depolarization due to phase-differences on larger particles. The third and imaginary part of the denominator of the equation is the radiation-damping correction which strongly decreases the field enhancement at large particles due to radiative losses. The real part of the dielectric constant of the metal, $\varepsilon_1(\omega)$ is responsible for the resonance peak position, whereas the imaginary part of the dielectric constant, $\varepsilon_2(\omega)$, is related to the width of the peak. The radiation damping for larger particles can also cause a broadening of the particle plasmon resonance.

For small particle volumes, the third order term of the denominator can be neglected. Then particle plasmon resonance occurs when the denominator of the polarization becomes zero in the expression

$$P = \frac{3(\varepsilon - 1)}{4\pi[\varepsilon(1 - k^2 a^2) + 2 + k^2 a^2]} E_o \quad (2.2.2)$$

The disappearance of the real part of the denominator in (2.2.2) creates the surface plasmon resonance, which leads to the field enhancement [6]

$$P_{res} = \frac{3(\varepsilon_{res} - 1)}{4\pi[\varepsilon_2(1 - k^2 a^2)]} E_o \quad (2.2.3)$$

where ε_{res} is the complex dielectric constant at the plasmon resonance frequency and ε_2 is the imaginary part of the dielectric constant of the metal at that frequency.

Before 1900, understanding the most striking properties of metals, such as the conduction of electricity and thermal conductivity had been very difficult. In 1900, Paul Drude successfully formulated a model for metallic properties based on describing free electrons in the conduction band like gas molecules. The Drude model uses the relative permittivity at infinite frequency $\varepsilon_D(\infty)$, the plasma frequency $\omega_p = \frac{de^2}{\varepsilon_0 m_{eff}}$, which depends on the effective electron mass m_{eff} , the electron density d , and the relaxation time Γ , which is determined by the collision of the free electrons with phonons, ions, and impurities, to explain the so-called free electron gas molecular behavior in the conduction band [7]. Therefore the dielectric function of certain MNPs can be described through a Drude model by [8]

$$\varepsilon_D(\omega) = \varepsilon_D(\infty) - \frac{\omega_p^2}{\omega^2 + i\Gamma_D \omega} \quad (2.2.4)$$

For smaller particles, the resonance is also broadened by surface scattering of the electrons, which can be included in the Drude description via ε_2 . The small size influence on the dielectric constants of a MNP can be approximately described by [9]

$$\varepsilon_2(\omega) = \frac{\omega_p^2}{\omega^2 + \omega_c^2} \left(\frac{v_F}{l_\infty} + \frac{v_F}{b} \right) + \varepsilon_2^{bound} \quad (2.2.5)$$

The first term of Equation (2.2.5) is the free-electron contribution, namely the Drude model (2.2.4), to the damping. ε_2^{bound} is the contribution of bound electrons. v_F is the Fermi velocity for the collision within the material. l_∞ means the electron free path in the material. b is the short axis of the particle boundaries. ω_c is the collision frequency within the material. Thus, as the length of the free path in the material is shortened by the smaller radius of the particle, the imaginary part of the dielectric constant increases. As can be seen from Equation (2.2.5), as ε_2 is increased due to a smaller particle size, b , this decreases the polarization, P_{res} , in Equation (2.2.3).

For general sizes of MNPs, the resonance condition is achieved when the denominator of the real part in Equation (2.2.1) vanishes such as

$$\varepsilon_1(\omega)(1 - k^2 a^2) + (2 + k^2 a^2) + \varepsilon_2 \frac{2}{3} k^3 a^3 = 0 \quad (2.2.6)$$

Then the field enhancement is limited by the imaginary part of the denominator in Equation (2.2.1). Increasing the particle size needs a more negative value of $\varepsilon_1(\omega)$ to retain the resonance condition. Because of the decrease of $\varepsilon_1(\omega)$ toward longer wavelengths this results in the red shift of the dipolar plasmon resonance (Figure 2.2.2). Generally, the real part of the dielectric constant of noble metals has negative values below the plasma frequency, whereas the imaginary part of the dielectric constant has positive values.

Figure 2.2.2: Schematic frequency dependence of the dielectric constant of a metal. $\varepsilon_1(\omega)$ is the real part of the dielectric constant for silver as function of wavelength. $\varepsilon_2(\omega)$ is the imaginary part of dielectric constant for silver.

As the size of the particle increases, higher modes of the plasmon resonance are excited, which is expressed by the secondary term of the denominator of Equation (2.2.1), $k^2 a^2$, and, for instance, a quadrupole mode will occur. The quadrupole

resonance is less sensitive to the particle shape and size than the dipole plasmon resonance [10].

2.2.2 Mie theory for spherical particles

The scattering of light by a sphere the size of the wavelength of the light is well described by Mie theory. Mie theory describes reflection, refraction, and interference of light from different locations on the sphere. Mie theory is derived from Maxwell's equation for the boundary conditions of a sphere. Extinction spectra, which describe the scattering plus absorption of light from a sphere can be calculated rather easily (Extinction = Scattering + Absorption). Mie theory describes the scattering of light by dust in air or by water droplets in clouds. Mie theory has to be used for spherical particles with a radius greater than about 1/20 the wavelength of light. The Mie description includes as a limiting case for smaller particles Rayleigh's equation for the scattering of light. When a small particle is exposed to an electromagnetic field whose wavelength is much longer than the diameter of the particle, every electron in the particle experiences the same phase of the wave, thus all of the electrons oscillate and scatter light with the same phase. However, when the particle size is larger than the wavelength of the field, electrons in different locations of the particle oscillate with different phase. This creates interference of the electromagnetic field from electrons in different parts of the particle (Figure 2.3.1). Therefore, Mie theory can be used to calculate the light radiation from oscillating electric dipoles, quadrupoles, octopoles and higher multipoles as the particle size increases.

Figure 2.3.1: Illustration of the effects contributing to Mie scattering.

Mie theory yields the scattered electromagnetic field as an expansion in vector spherical harmonics [7]. As the result, the total extinction coefficient Q_{ext} and the scattering coefficient Q_{sca} can be calculated with the help of the Mie scattering coefficients a_n and b_n .

$$Q_{ext} = \left(\frac{2}{x^2}\right) \sum_{n=1}^{\infty} (2n+1) \text{Re}(a_n + b_n) \quad (2.3.7)$$

$$Q_{sca} = \frac{2}{x^2} \sum_{n=1}^{\infty} (2n+1) (|a_n|^2 + |b_n|^2) \quad (2.3.8)$$

where the size parameter x is

$$x = ka = \frac{2\pi na}{\lambda} \quad (2.3.9)$$

where a is the particle radius and n is the refractive index of the medium. Re is the real part of the complex function. From Equation 2.3.7 and 2.3.8 it is clear that the relative

contribution to the extinction spectrum of absorption and scattering are changed by changing the particle size.

Finally, the scattering coefficient a_n, b_n are expressed in terms of Bessel functions

$$a_n = \frac{n\psi_n(nx)\psi'_n(x) - \psi_n(x)\psi'_n(nx)}{n\psi_n(nx)\xi'_n(x) - \xi_n(x)\psi'_n(nx)} \quad (2.3.10)$$

$$b_n = \frac{\psi_n(nx)\psi'_n(x) - n\psi_n(x)\psi'_n(nx)}{\psi_n(nx)\xi'_n(x) - n\xi_n(x)\psi'_n(nx)} \quad (2.3.11)$$

where $\psi_n(nx)$ and $\xi'_n(nx)$ are the *Riccati-Bessel* functions defined as $\psi_n(\rho) = \rho j_n(\rho)$, and $\xi_n(\rho) = \rho h_n^{(1)}(\rho)$. $j_n(\rho)$ and $h_n^{(1)}(\rho)$ are spherical Bessel functions of the first and second kind. The derivatives of the scattering coefficient can be expressed for computational calculation such as

$$\psi'_n(x) = \psi_{n-1}(x) - \frac{n\psi_n(x)}{x} \quad (2.3.12)$$

$$\xi'_n(x) = \xi_{n-1}(x) - \frac{n\xi_n(x)}{x} \quad (2.3.13)$$

For particles in an ambient medium other than air, the refractive index n is the relative refractive index of the complex refractive index of the metal sphere, n_m , and the host medium refractive index, n_0 ,

$$n = \frac{n_m}{n_0} \quad (2.3.14)$$

a_n and b_n express amplitudes of the scattered electric and magnetic fields for each order of the field expansion. Note that a_n and b_n disappear as the refractive index, n , in Equation (2.3.14) approaches 1, i.e. the scattered field also vanishes. So, the total transmittance and the extinction coefficient of a sphere of arbitrary radius can be determined with Mie theory. Because this theory does not assume a particular dielectric constant, it can be used with metallic spheres and predict resonant scattering and absorption due to surface plasmon resonances. Mie theory calculation can be adopted to ellipsoidal shapes[11], infinite circular cylinders [7] and nanoshells [12].

2.2.3 Various computational methods for Non-spherical MNPs

Non-spherical particles such as triangles [13, 14], pentagons [13], decahedra [15], stars [16], rods [17], cubes [18] and truncated tetrahedrons [19] have been fabricated and characterized for optical properties. Non-spherical metal particles have similar optical properties, but, in general, Mie theory can no longer be applied. For instance, nanorods generally have transversal (across the rod) and longitudinal (along the rod) localized surface plasmon excitations depending on the transversal and longitudinal polarization direction of the exciting field. The longitudinal surface plasmon in the rod is red-shifted from those of similar sized ellipsoids [17]. Transversal surface plasmons in nanorods, which are independent of longitudinal surface plasmons have a much lower absorption coefficient and the resonance is located at shorter wavelengths. Although the transversal cross section of the rod resembles a sphere or ellipsoid in cross section and has been calculated by Gans' formula [17] which was derived from Mie theory for a single ellipsoid, there is still a quantitative discrepancy between experimental values and the modeling results due to the aspect ratio of the rods, aggregated rods, and polydisperse rod sizes [17, 20].

The electromagnetic field distribution around other non-spherical particles, such as a truncated tetrahedron, is very different from that of a spherical shape [10], with intense quadrupole contributions, which are absent for spherical particles of roughly equivalent sizes [21]. Very intense electromagnetic fields are found near the tips of the particle along the polarization direction. This is called local field effect in non spherical particles. The dipole resonance has maximum enhancement at the tips, while for the quadrupole resonance the enhancement is shown at the sides [21].

The dipole resonance for the triangle shape is also substantially red-shifted compared to a spherical particle of same size. The sensitivity of the resonance peak

positions to geometrical changes in the tip is very strong, so when the triangle corners are more rounded, the spectral peak shifts to blue again [13]. Similarly, for thicker triangle particles the spectral peak shifts to the blue region which is opposite of the behavior for the spherical particles [19].

Since Mie theory does not generally hold for non-spherical particles, different numerical methods have to be used to simulate theoretical aspects and compare with the experimental results, such as the T-matrix method [22], Discrete Dipole Approximation (DDA) [10, 21, 23], the multiple multipole method (MMP) [24], Finite-element method (FEM) [25], surface integral equation (SIE) [26], the method of moments (MOM) [27], and the finite difference time domain method (FDTD) [8, 28-30].

Approaches for numerical calculations of the electromagnetic field for non-spherical shapes fall in roughly three categories. One is calculating the scattered field by solving the differential equations of Maxwell equations in the time domain or in the frequency domain with appropriate boundary conditions. FEM belongs to the differential equation approach method. The other is integrating the volume or surface for the total electric field everywhere in space with the incident field and the total field using Maxwell's equations. The scattered field is calculated by subtracting the incident field from the total field. DDA, MOM and SIE belong to the integration method category. A third category includes FDTD, T-matrix method, and hybrid techniques which merge FDTD-FEM, or FEM-MOM, etc.

Near field simulation around non-spherical MNPs is very helpful to understand the electromagnetic field behavior around MNPs and has been approached by many numerical analysis tools such as DDA [10], FEM-MOM [31], and FDTD [8, 32-34]. For example, computational prediction in the near-field of the electric field of arbitrary shaped particles was calculated by DDA [10]. The region of high field intensity is

localized to the high curvature periphery of the spheroidal particle and the tip of the tetrahedron particle. The tetrahedron particle has the highest field intensity compared to spherical or spheroid particles. As mentioned earlier, this is called a local field enhancement effect in the tip region of the tetrahedron (Figure 2.4.1). The decay length of the localized surface plasmon of the triangle is dramatically decreased compared to the exponential decay length of the conventional SPR (Figure 2.4.1 (c)).

Figure 2.4.1: DDA simulated electric field contours with $|E|^2$ for various shapes. (a) The innermost contour represents the grid boundaries of a 30nm sphere. The drop in intensity is from 50 to 1. (b) 2:1 spheroid has high field intensity to the high curvature periphery of the particle. The drop in intensity is from 125 to 1. (c) The truncated tetrahedron has high field intensity near the tip. The drop in intensity is from 500 to 1. [10]

There are many aspects such as numerical accuracy, computation time and resource requirements, applicability to arbitrary particle shape and size, capability of near field simulation, and far field calculation to judge which numerical tools are chosen in the computational modeling for non-spherical MNPs. Many computational tools have their own advantages and disadvantages for numerical simulation. However, the details of the various available computational tools are not covered in this thesis.

For this thesis, FDTD using XFDTD 6.4® which is supported by REMCOM (www.remcom.com) and FEM using FEMLAB 3.3a® which is commercially available

from COMSOL (www.comsol.com) were chosen as the computational modeling tools to support our experimental results. These tools were chosen because of their capability of near field and far field calculation in 3D, software availability, computational performance, time, cost, and good user interface.

FEM solves unknown electric or magnetic fields at discretized small volume cells called elements or mesh nodes with the partial differential equation for the vector Helmholtz equation. As a result, FEMLAB 3.3a® can solve the scattered time harmonic propagating electric or magnetic field. Interpolation is used to fill the data between the nodes from the point of interest to each node. Thus assigning an optimized mesh size and shape is very important for the numerical accuracy in FEM simulations because of the interpolation. As the computational mesh is finer, the numerical calculation accuracy is also improved. Typically, the mesh size should be at least 10 times smaller than the smallest wavelength for accurate calculation. Therefore, the FEM result is dependent on the meshing algorithm. This mesh size and shape can be non-rectangular and non-equidistant in FEM. This is the fundamental advantage for FEM method. With this advantage in FEM, the advantage of using FEMLAB 3.3a® is that it has a powerful user graphic interface, allows time and distance variation in 2 D and 3D simulation including near field and far field calculation, and it has good MATLAB® compatibility. The disadvantage of FEMLAB 3.3a® is that it is not fully capable of calculating total fields. It is only usable in scattering field simulation with free space. Dielectric environments such as water/glass half-space simulation results are not disturbance-free in FEMLAB 3.3a®.

In 1966, a solution for Maxwell's curl equations was suggested using the finite-difference time-domain (FDTD) technique [35]. FDTD has been in extensive use only since the end of the eighties due to the high computational and memory costs of the

method [36]. With modern powerful computers and low computational costs, the FDTD technique has gained much attention for solving electromagnetic problems.

FDTD calculates the scattered field in the time domain by solving Maxwell's time-dependent equations. The space and time derivatives of both fields in FDTD are approximated by the space and time discretization with differences in a stair-casing way. The electric field and magnetic field are assumed interleaved around a cell called the Yee cell (Figure 2.4.2). Every E field is located at the edges of a Yee cell, and every H field is located at the cube faces.

Figure 2.4.2: Illustration of a Yee cell for FDTD. The electric field is located in the edges of the cube (blue arrow), and the magnetic field is located at the cube faces (bold red arrow).

Yee defines a regular orthogonal grid of coordinates (i, j, k) as $(i, j, k) = (i\Delta x, j\Delta y, k\Delta z)$, where $\Delta x, \Delta y$, and Δz are the actual grid separations [35].

A discrete space and time function can be written as $F^n(i, j, k) = F(i\Delta x, j\Delta y, k\Delta z, n\Delta t)$, where Δt is the time increment, and n is the time

index for central difference approximation of derivatives. The spatial and temporal derivatives of the function can be written, using central finite difference approximations as

$$\frac{\partial F^n(x_i, j, k)}{\partial x} = \frac{F^n(x_i + 1/2, j, k) - F^n(x_i - 1/2, j, k)}{\Delta x} \quad (2.4.1)$$

$$\frac{\partial F^n(i, j, k)}{\partial t} = \frac{F^{n+1/2}(i, j, k) - F^{n-1/2}(i, j, k)}{\Delta t} \quad (2.4.2)$$

with space increments, $\delta = \Delta x = \Delta y = \Delta z$.

These difference approximations (2.4.1) and (2.4.2) can be applied to Maxwell's equations for FDTD calculations as [28].

$$\begin{aligned} E_x^{n+1}(i+1/2, j, k) = & E_x^n(i+1/2, j, k) + \frac{\Delta t}{\Delta x \cdot \sqrt{\epsilon_0 \mu_0}} [H_z^{n+1/2}(i+1/2, j+1/2, k) - \\ & H_z^{n+1/2}(i+1/2, j-1/2, k) + H_y^{n+1/2}(i+1/2, j, k-1/2) - \\ & H_y^{n+1/2}(i+1/2, j, k+1/2)] \end{aligned} \quad (2.4.3)$$

$$\begin{aligned} H_x^{n+1/2}(i, j+1/2, k+1/2) = & H_x^{n-1/2}(i, j+1/2, k+1/2) + \\ & \frac{\Delta t}{\Delta x \cdot \sqrt{\epsilon_0 \mu_0}} [E_y^n(i, j+1/2, k+1) - E_y^n(i, j+1/2, k) + E_z^n(i, j, k+1/2) - E_z^n(i, j+1, k+1/2)] \end{aligned} \quad (2.4.4)$$

If the cell size Δx is chosen once, then the time step Δt has to be smaller than $\Delta t = \frac{\Delta x}{\sqrt{n} \cdot c_0}$, where n is the dimension of the simulation, \sqrt{n} is approximately 2 in 3D and c_0 is the speed of light in free space. Practically the time step is approximately half of the cell size [28].

From (2.4.3) and (2.4.4), it is clear that the electric field time derivatives are dependent on the magnetic field space variation and vice versa in the Yee cell. E and H values at the grid points for the previous and current time steps must be calculated and stored at the next time step which is called leap-frog algorithm. Therefore, increasing the

memory requirement proportional to the total number of mesh points is essential. This rectangular grid calculating method can also increase numerical errors, which can be minimized by making the grid size smaller.

Since FDTD solves the E and H field with Maxwell's equations in the time domain, the time responses of the electric field and the magnetic field in the medium are required. However, if the complex permittivity has a negative value in the real part or imaginary part, like gold and silver, then the FDTD calculation will become unstable. To avoid that issue, Drude or Lorentz model approximations have been adopted to fit the experimental dielectric constants for use in FDTD [8, 34, 37].

Since FDTD is a time varying field calculation, it is intuitive, simple, and easy to implement. Thus it is a good tool to illustrate and understand the computational results in 3D for the near field and the far field. Further details of the algorithm and theory for FDTD are covered in Chapter 5.

To overview FEM and FDTD methods, there are many similarities and differences between FEM and FDTD. The electromagnetic fields in FEM and FDTD are propagated through a discretized volume, called elements or mesh. This element size should be 10 to 20 times smaller than the smallest wavelength. The difference in the meshing method between FDTD and FEM is that FDTD has constant intervals for a given direction and FEM has irregular mesh sizes.

Both FEM and FDTD initially have unknown electric and magnetic fields at the mesh nodes. To limit the number of unknown fields at mesh nodes to a certain size, FEM and FDTD must be implemented in a finite computational domain due to computational accuracy, time and resources.

Therefore, certain absorbing boundary conditions (ABC) for FEM and FDTD must be required at the boundary of the computational space to limit the computation size

and truncate the undesired reflections that otherwise would go back into the computational space. Mostly Perfectly Matched Layer (PML) techniques are used in both FEM and FDTD [38].

The most advantageous feature of FEM and FDTD is that they can be applied to arbitrary and inhomogeneous particle shapes and sizes, while some of the integral equation methods are limited to only a few model shapes and sizes.

FEMLAB 3.3a® for FEM and XFDTD® for FDTD can simulate the near field and far field in 2D and 3D. With near to far zone transformation techniques, such as Stratton-Chu formula or Green's function [39, 40], it is possible to compute the scattered far zone field. In the Stratton-Chu formula, E_p is the calculated far field at point P.

$$E_p = \frac{jk_o}{4\pi} r_o \times \int [n \times E - \eta_o r_o \times (n \times H)] \exp(jk_o r \cdot r_o) dS \quad (2.4.5)$$

where r_o is the unit vector pointing from the origin to the field point p, n is the unit normal to the surface S, η_o is the free space impedance, k_o is the free space wave number, r is the radius vector of the surface S. The far field point p is normally taken at 1 m with spherical coordinate position θ and ϕ . The far field intensity pattern is given by $|E_p|^2$.

In this thesis, 3D FDTD simulations and 2D FEM cross-sectional in-plane simulations were used to explore the LSPR properties in the sharp features of the non-spherical MNP and compare the simulated and experimental results.

2.2.4 Sensitivity of MNP plasmonic sensor to the dielectric environment

There is growing attention to the study of the localized particle plasmonic sensor used as a detecting sensor for dielectric environmental changes. First, it has been shown that colloidal gold particles can be used as detecting agents [41, 42]. When colloidal gold particles coated with an antibody interact with a protein ligand, the extinction peak of the

surface plasmon resonance is red-shifted from 544 nm to 547 nm wavelength by slight changes in the refractive index at the colloidal gold surface [41]. Observing the kinetics of the binding of a protein ligand to an antibody immobilized on the surface of colloidal gold is even possible by using the fixed wavelength of 600 nm to the red of the peak. The smallest tested ligand size was 15 kDa for the anti-human heart fatty acid-binding protein (hFABP) [41]. Colloidal gold particles were also used as immunoassay and compared with other existing methods [42]. From these reports, it is understood that the SPR wavelength change is directly related to the diameter of the spherical particle and the refractive index change in the medium as predicted by equation (2.2.1) and Mie theory. Mie theory predicts a linear relationship between the peak position of the plasmon resonance and the refractive index change of the surrounding medium for a spherical MNP. This was experimentally shown using 0.04 refractive index steps [43], and similarly for non-spherical MNPs, specifically in triangular MNPs.

One group calculated that in quasistatic approximation the sensitivity of the resonance to bulk refractive index changes is merely a function of the peak wavelength [44] regardless of the structural features of the particles. The sensitivity of the peak wavelength, λ^* , to the change in refractive index n is found to be a linear function of peak wavelength

$$\frac{d\lambda^*}{dn} = \frac{2}{n} \lambda^* + \frac{2}{n} \frac{\varepsilon_x}{m} \quad (2.5.1)$$

where $\frac{2}{n}$ is the slope and ε_x is the intercept and m the slope for the linear approximation of the real part of the dielectric function of gold or silver. The authors showed that gold nanodisks, nanoshells, and nanocylinders have the same sensitivity as long as they have

the same peak positions. However, this applies only to the bulk refractive index changes. Near-field contributions from particles with sharp features such as edges, corners, or apexes, which show enhanced electric fields, have been shown to contribute significantly to the sensitivity. The above equation may therefore not hold for the near field in non-spherical MNPs, and in larger particles, where the quasi-static approximation may no longer apply.

Nanocubes, which are an example of non-spherical MNPs, and which can have hollow interiors and sharp corners, have been synthesized and characterized [18, 45]. The resonance position of the cubes is dependent on the size. Smaller cubes have the peak positions of the resonance at short wavelengths, while bigger cubes have the resonance at longer wavelengths [18]. Another set of experiments measured the sensitivity for similar nanocubes under different dielectric environments at an interface [45]. They found two plasmon resonance peaks when the cubes touched a glass substrate. One peak was blue and the other peak was found to be red. FDTD near field simulation showed that the blue peak is related to large fields from the cube corners away from the substrate surface (top corners) and the more red peak is related to large fields from the cube corners toward to the surface (bottom corners). These two peaks both have an increased sensitivity to bulk refractive index changes. However, the blue peak has larger peak shifts than the red peak under the same bulk dielectric environmental conditions, because of the substrate influence on the near-field distribution and intensity. Thus it is understood that different polarization direction, the presence of corners and the position with respect to the substrate, as well as the size, thickness of the MNP, and most importantly near field intensity are all critical for plasmonic sensing.

Not only the bulk refractive index change, but also the localized refractive index change gives a linear shift of the absorption peak [3, 14, 46]. Linear response of localized

plasmon resonance to alkanethiol chain length dependency has been shown with triangular tetrahedron pyramid [3, 46] and triangular nanoprism [14]. As the adsorbate layer thickness [47] or chain length increases [3, 14, 46], the peak shift is also increased linearly in both non-spherical structures. After surface modification with hexadecanethiol on the MNPs, the bulk refractive index sensitivity drops from 196 nm /RIU to 159 nm /RIU [46]. It is explained by the near field intensity decrease at the sharp edges and corners due to the chemical modification of the surface. Near field numerical simulation with DDA supports these experimental results. It shows that the dielectric shift is largest where the near field is largest [46, 48]. FDTD simulations for near field scanning optical microscopy (NSOM) probes also show that the enhancement in electric field strength from localized surface plasmon resonance in the vicinity of sharp apex is much stronger than in other areas of the MNPs, due to strong field confinement [33].

Therefore, the understanding of the relationship between near field enhancement and plasmonic sensing application is a crucial step for developing label-free sensing techniques. The understanding of non-spherical MNPs for both bulk and local refractive index changes and the associated sensitivity is also important.

Chapter 3: Fabrication of carbon based template-stripping method for large scale nanopatterned atomic scale flat surfaces

3.1 INTRODUCTION

Non-spherical MNPs with sharp features enhance the electric field at corners or edges [1]. However, sharp features like corners and edges often are not preserved in solvents or during chemical modification. For applications as a reliable sensor the shape has to be preserved, since changes in shape influence the resonance peak position as well as the sensitivity to bulk and local changes in the refractive index of the environment [2, 3].

Although it is possible to produce various non-spherical MNP shapes with sharp features, these features are never perfectly sharp after chemical modification or during chemical synthesis. For instance, to achieve reliability and reproducibility, triangular shapes of truncated tetrahedrons have to be annealed in a solvent or be annealed thermally, which leads to rounded tips and edges [3, 4]. Triangular nanoprisms [5], made by chemical synthesis, also have significant changes in shape that influence the resonance peak. The nanoprisms often have rounded apexes and exposure to ethanol for 12 hours for chemical functionalization leads to a blue shift induced by solvent annealing. DDA calculations show that, as the sharp tip of the nanoprism is snipped, the resonance spectrum is less broad. The authors suggested that if the tips are well protected, then the nanoprism sensing performance will be improved, and a method for protecting the tips is under development [5]. We have looked for a technique that could preserve sharp corners and edges of non-spherical MNPs. The ultraflat nanosphere lithography (UNSL) technique [6] embeds the MNP partially into a very flat substrate surface and so preserves the MNP shapes.

Additionally, ultraflat surfaces have versatile usages. For examples, ultraflat surfaces made from mica, highly oriented pyrolytic graphite (HOPG), and silicon play a crucial role in many scanning probe experiments [7, 8], and in protein [9] and DNA [10-12] adsorption investigations. Limitations in material properties, such as conductivity, surface chemistry, and the need for flat heterogeneous materials, have led to the development of template-stripping methods. These mostly use flat surfaces, such as mica or silicon, as starting substrates to evaporate the desired materials onto, and retrieve a flat surface after removing the original substrate [13]. Evaporation and sputtering techniques are easy approaches to create surfaces of the desired materials, but high surface energies can produce irregular grains with topography in the several-nanometer range [14]. Although control of thermal evaporation rates, the choice of the substrate, and thermal annealing can reduce roughness [14-16], surfaces of evaporated materials often do not achieve the flatness seen with mica, HOPG, and silicon. Template stripping is a powerful and simple technique to create ultraflat surfaces with evaporated materials. It allows for a variety of materials to be used as long as the adhesion forces between the flat template and the desired sample are weaker than the adhesion forces at any other interface within the final material, such as the surface material-to-glue interface and interfaces between different materials in heterogeneous samples. Besides mica, glass [17], silicon [18], and even gypsum [19] have been used for template stripping, with the resulting surfaces showing good flatness. Examples of template-stripped ultraflat surface materials are gold [20-27], titanium oxide [28, 29], and platinum [30, 31] for homogeneous surfaces, and gold-glass, silver-glass [6], gold-silver [32], and cobalt-gold-titanium [33] for composite surfaces. Applications that require ultraflat sample surfaces range from the study of self-assembled monolayers on gold [20, 22], supported or tethered lipid bilayers

[34] and electrodes [35], Langmuir-Blodgett films [18], and single molecule studies [36], to the study of model surfaces for protein and cell adsorption [28, 37] .

Although a roughness of less than 1 nm root mean square (rms) has been easily achieved with this method over relatively large areas, for many surface materials mica had to be used as the template, and the final stripping process was often incomplete and irreproducible, leaving thin residual mica shards. Therefore a variety of improvements have been developed that allow for a controlled, complete, and reproducible removal of the template. Ultraflat gold surfaces could be detached from mica using tetrahydrofuran (THF), but transparent glues, in particular, would not survive the treatment [22]. For gold surfaces, the glue could be replaced with cold welding at high pressure [24] or by solid-state bonding at elevated temperatures [27]. Alternatively, gold can be stripped from mica templates using thiol solutions, but at the expense of the gold film being coated with a thiol film [25]. Sacrificial layers, such as sputtered carbon films, offer an alternative by allowing for an easy detachment and removal by oxygen plasma [28, 29]. However, mica still has to be stripped mechanically, and, while on thick homogeneous films the residual few-nanometer-thick mica shards may be removed by prolonged plasma etching, on heterogeneous films this will lead to uneven etching or even the removal of one material component. Other materials can be used for the mechanical stripping process, but the template needs a certain bending tolerance during the mechanical stripping or the forces that have to be applied will become too large. The problem of too much force makes thin glass slides and silicon wafers less attractive, because, like mica, they break easily, and thick glass slides are too rigid to allow stripping.

The new fabrication method described in this chapter improves the ultraflat nanosphere lithography (UNSL) technique developed to create nanopatterns over cm^2 -areas of two materials without associated topography, which originally used mica as the

template [6]. The improvements were needed because the residual mica shards had a significant influence on the LSPR peak position, thereby making measurements very noisy. This chapter presents here a technique to improve template stripping in general. The focus is on UNSL in particular to achieve the goal of residue-free template-stripped surfaces, while also being versatile in the use of materials for the final surface and allowing for optically transparent samples. The following requirements had to be met: (1) the template had to be flat and somewhat bendable but “unbreakable”, (2) the template had to be very hydrophilic with water contact angles below 10° to allow for good nanosphere self-assembly, (3) the stripping had to be gentle enough and well controlled enough to accommodate differential adhesion between the different materials of the patterned surfaces, and (4) the resulting surface had to be free of any contamination so that pattern and background could be functionalized independently with the chemical functionalities of choice. After outlining the fabrication process, we demonstrate the power of this improved UNSL technique for nanopatterning self-assembled monolayers (SAMs), for creating surfaces to be used as sensors, and for combining nano- and soft lithographic techniques.

3.2 EXPERIMENTAL METHODS

Materials: Polystyrene nanospheres of 500 nm, 400 nm, and 300 nm diameter were purchased from Interfacial Dynamics Corporation (Portland, OR). De-ionized water with a resistivity of at least $18.0 \text{ M}\Omega \text{ cm}$ was used. Methanol and ethanol (Fisher Scientific, Houston, TX), and 1-Hexadecanethiol (Aldrich, Milwaukee, WI) were used as purchased. Optically transparent, low-viscosity epoxy, Epo-Tek #302-3M (Epoxy Technology Inc., Billerica, MA) or 20-3068 (Epoxies, Etc, Cranston, RI) was used for all bonding of surfaces. Plain microscope slides (1 mm thick, $2.2 \times 4.4 \text{ cm}^2$) (Erie Scientific,

Portsmouth, NH) and cover slips (0.13-0.16 mm thick, 2.2 x 2.2 cm²) and PVC slides (1mm, 2.5x2.5 cm²) (all VWR) were used for substrates and templates. Tungsten vapor deposition boats and carbon crucibles and silicon dioxide (SiO₂) were purchased from Kurt J. Lesker Company (Clairton, PA). Silver (99.99%, 1-3 mm diameter) and gold (99.99%, 6.35 mm) were purchased from Alfa-Aesar (Ward Hill, MA), and carbon rods were purchased from Ted Pella Inc. (Redding, CA).

Template preparation: Two glass cover slips that had been glued together for easier mechanical handling were used as the template. Before use, the template was rinsed with de-ionized (DI) water and dried with N₂ gas. An amorphous carbon layer was deposited on the glass in a thermal evaporator (Edwards 306) at 1.5 x 10⁻⁵ mbar. The thickness of the carbon layer was typically 8-10 nm, as determined from steps in test samples. The carbon layer was made hydrophilic by a glow discharge in the same system. Coarse carbon particles and dust on the carbon film were removed under a stream of dry nitrogen.

Nanosphere deposition: We adopted a method to deposit nanospheres onto a substrate by moving a cuvette horizontally across the substrate that had been shown to produce large areas of hexagonally packed nanospheres. A home-built micro-translation stage with two independent stepper motors to control the height and lateral movement of the cuvette was used to fabricate the nanopatterns. 0.4 x 20 mm cross-section cuvettes were fabricated by gluing two glass slides at a defined distance with epoxy. A carbon-coated glass template was attached to a glass slide with double-sided tape for easier handling, and rested horizontally on the bottom translation stage underneath the cuvette. The cuvette was filled with 160 µl of the undiluted nanosphere suspension, and positioned at a proper height from the mica to form a meniscus. Moving the cuvette horizontally led to the formation of a close-packed monolayer of the polystyrene

nanospheres over the full $2.5 \times 2.5 \text{ cm}^2$ carbon layer. Lateral speed and cuvette height need to be adjusted to match relative humidity and temperature conditions.

Nanoparticle composite fabrication: The densely packed monolayer of spheres was used as a mask for the thermal evaporation of gold or silver at a pressure of about 2×10^{-6} Torr and a rate of 5 \AA/s in a thermal evaporator (Denton Vacuum DV-502A, Moorestown, NJ). The desired thickness of the deposited metal was controlled by a quartz crystal monitor. After thermal metal evaporation, the spheres were removed from the carbon layer by sonication for 1 min in DI water with 3 degauss force in a sonication bath (VWR Aquasonic Model-75D). Samples were rinsed in DI water and dried in a stream of N_2 gas. Following the lift-off of the spheres, 500 nm of SiO_2 was deposited onto the surface at 2×10^{-6} Torr in an electron-beam evaporator (Edwards Auto500, Crawley, UK) at a rate of 5 \AA/s .

Template stripping process: A cleaned glass slide was glued with epoxy to the freshly evaporated nanocomposite film to provide mechanical support. In order to avoid air bubbles that developed from dewetting in the glue between the glass support and the evaporated SiO_2 , the glue was applied in two steps. First, a thin layer of the epoxy was deposited and cured on the evaporated SiO_2 surface to seal the SiO_2 . Then a second layer of epoxy was used to attach the support glass slide to the first epoxy surface. A PVC substrate was glued to the glass side of the original carbon-glass substrate to facilitate the lift-off step. The epoxy was cured in all curing steps at 80°C for 3 hours. After curing, the PVC-glass-carbon substrate was peeled off from the glass substrate with a scalpel, leaving the desired sample surface coated with a carbon film.

Removing residual carbon by O_2 reactive ion etching (RIE): Oxygen plasma was used for removing residual carbon from the stripped sample surface in a March CS-1701 Reactive Ion Etcher (Concord, CA), at 100 W, 20 sccm, for 4 min, unless otherwise

noted. Finally, the reactive ion-etched UNSL surface was cleaned before use by sonication for 1 min in DI water and then dried in a stream of N₂.

Sample characterization: Samples were characterized with AFM (Asylum Research MFP 3D, Santa Barbara, CA) in contact mode under ambient conditions at scan speeds of 10-80 $\mu\text{m/s}$ using silicon nitride probes (NP-20, Veeco Metrology, Santa Barbara, CA). For height characterization and rms, the surface was measured over a $2 \times 2 \mu\text{m}^2$ area at scan speeds in the range of 1.5-4 $\mu\text{m/s}$. Ultraviolet–visible (UV-Vis) extinction spectra, measured in a Cary 5E UV-Vis-IR spectrophotometer (Varian), were used to follow the changes in the coating of the gold or silver particles.

Thiol functionalization: Au/SiO₂ UNSL samples were incubated in a 3 mM ethanolic solution of hexadecanethiol (HDT) (Aldrich) for up to 24 hours or as specified. Samples were rinsed in ethanol and dried under a stream of nitrogen. For microcontact printing, polydimethoxysilane (PDMS) (Sylgard 184, DuPont) was poured onto a template of an SU-8 (2015, Microchem) pattern on a silicon wafer and cured at 90 °C for 1 h. The PDMS stamp was then oxidized in an O₂ plasma for 30 s at 50 W and 20 sccm to minimize the transfer of PDMS residue to the glass areas [38]. A 0.1 mM ethanolic HDT solution was applied to the surface of the stamp and dried under a stream of nitrogen. The stamp was brought in contact with the surface for up to 2 min. Upon stamp removal, the sample was immediately rinsed in warm ethanol (~ 30 °C) and sonicated for 1 min at 9 degauss, and finally dried under a stream of nitrogen.

3.3 RESULTS AND DISCUSSION

3.3.1 Sample fabrication and characterization

Although Rossetti *et al.* [29] introduced a carbon layer of 6 nm to 20 nm to template-strip titanium oxide against a mica substrate, the prolonged high-power oxygen

plasma treatment needed to remove remaining mica shards from the titanium oxide was not compatible with the composite materials used here. Figure 3.1 shows an example of a thin mica sheet that remained on a classical UNSL sample with a mica template that had been coated with a hydrophilic carbon layer, with the plasma etch time limited so that exposed areas would not be overetched. The limitation of the etch times will be explained in more detail below.

Figure 3.1: AFM image of mica residues on a classical UNSL sample with an additional carbon film on the mica template. The sample was oxygen plasma treated for 150 s. Mica shards (light area) of 9 nm (as shown here) or larger thickness can remain, covering the intended surface (dark area), and are not removed at the etch times or powers used to preserve exposed areas.

Because mica is so brittle, a different template material was necessary to assure complete template removal. Glass slides are not elastic enough to allow mechanical lift-off, glass cover slips are bendable but break easily, and PVC cover slips are not smooth enough, we developed the new UNSL procedure shown in Figure 3.2. A pair of glass cover slips, glued together, were coated with an 8-10 nm thick layer of amorphous carbon

that was made hydrophilic by glow discharge. The resulting surface had a flatness comparable to glass. The carbon layer bonds strongly enough to the glass slide so that it is not removed by organic solvents or sonication. Polystyrene nanospheres were deposited onto the carbon surface to give a hexagonally close-packed monolayer of spheres that forms the mask through which material 1 is deposited by thermal or electron-beam evaporation. The density of MNPs so created was approximately 32,000 particles/mm². The spheres are removed by sonication in water, followed by the deposition of material 2, also by evaporation. Here we used gold or silver for material 1 and SiO₂ as material 2, but we have used other materials also. In contrast to original UNSL, no chromium layer is needed for the bonding of the gold or silver to the SiO₂. A glass slide is glued to the material 2 side for mechanical support of the final sample. The template is further reinforced before the mechanical stripping procedure by gluing a PVC cover slip to the bottom side, which also removes possible glass shards. The fracture occurs in the carbon film, leaving a thin carbon residue on the final composite surface. This residual carbon film is removed in an O₂ RIE step to expose the nanopattern of embedded nanotetrahedrons of gold or silver in a SiO₂ matrix. The sample is transparent but shows surface plasmon resonance (SPR) absorption due to the gold or silver metal nanoparticles.

We optimized the etching process and characterized its influence on the quality of the UNSL surface. The O₂ RIE process etches the carbon with a linear rate depending on the plasma power as determined by the absorption at 400 nm for a non-patterned carbon-coated glass substrate (Figure 3.3a). For all the following experiments we have picked a power of 100 W, corresponding to an etch rate of close to 0.67 nm/s. However, the same process on an UNSL surface requires more time as shown in Figure 3.5a for a Au/SiO₂ UNSL at 500 nm wavelength for the standard etching parameters. This

significant difference in the etching rate may be due to a different interaction of the evaporated materials with the carbon.

Figure 3.2: A schematic outline of the fabrication procedure of the new UNSL. The process begins with the deposition of an 8-10 nm hydrophilic carbon layer on a clean glass slide. Polystyrene nanospheres are deposited on the carbon layer to form a hexagonally closed-packed monolayer. Material 1 (here gold) is thermally evaporated onto the nanosphere mask. The spheres are removed, leaving material 1 nanoparticles, and in a second evaporation step a thick film of material 2 (here SiO_2) is deposited. A mechanical support (glass slide) is glued to the silicon dioxide layer. To facilitate the complete removal of the template, the original glass cover slip is supported by a PVC slide. The template is removed mechanically, and the carbon layer is removed by oxygen RIE, revealing an embedded truncated tetrahedron metal nanoparticle MNP in a matrix of material 2. Large areas (cm^2) can be fabricated with nearly atomically flat surfaces.

A more detailed picture of the etching process can be gained from UV-Vis spectroscopy and AFM, because the metal nanoparticles in the transparent samples show a localized surface plasmon resonance (LSPR), which is sensitive to the adjacent

material's refractive index. Figure 3.3b shows the SPR spectra at different etch times for a Au/SiO₂ UNSL sample. The SPR peak is strongly damped and far to the red before the etching, and a raised baseline indicates strong overall absorption from the carbon layer. With increasing RIE processing time, the peak position shifts to the blue as expected for a decreasing carbon film thickness, before a slight red shift when ablation of the UNSL sample sets in. This peak position shift to the blue and eventually to the red is seen for Au/SiO₂ and Ag/SiO₂ (Figure 3.3c), but while the minimum in the blue shift with etching time is very flat and broad for gold, it is much narrower for silver, indicating that silver is oxidized.

Figures 3.3d-h show AFM topographic images of the UNSL surface at three stages of the etching process: with the carbon layer (Figure 3.3d), with the carbon layer removed and the pattern intact, and with overetching for the Ag/SiO₂ (Figures 3.3e-f) and the Au/SiO₂ (Figure 3.3g-h) samples. After template removal, but before RIE, the carbon layer is smooth with the occasional hole, suggesting that the rupture during the stripping procedure is mostly along the carbon-glass interface. Exposure of the sample to 270 s of O₂ RIE creates a surface with the gold nanopattern having a topography of about 1 nm height. The overall roughness of the Au/SiO₂ UNSL sample is 0.76 nm root-mean-square (rms) over 2 μm^2 , and 1.0 nm over 20 μm^2 . After 330 s of RIE the overetching increases the roughness to 3.2 nm rms over 2 μm^2 , possibly due to the preferential ablation of the SiO₂. Although an increase in roughness is seen at long etching times, the AFM results confirm the UV-Vis results that Au/SiO₂ UNSL is relatively insensitive to overetching.

In contrast the Ag/SiO₂ UNSL surface is not quite as smooth as the Au/SiO₂ surface after 150 s. A 2 nm topography is associated with the nanopattern, corresponding to a roughness of 1.1 nm rms over 2 μm^2 . The 2 nm topography can be explained by the oxidation of silver, which has been shown to increase the volume of silver particles [39].

Longer etching times again lead to overetching and to the partial or total removal of the silver nanoparticles, and the formation of holes in the surface of the sample.

The carbon-based UNSL procedure yields ultraflat nanocomposite surfaces containing one nanopatterned material embedded in a second material with a free choice of materials as long as both materials can be bonded well enough to survive the lift-off of the template. Surfaces are created without template residues over the size of a typical cover slip. The etching process allows for the complete removal of the carbon from the template, and etch conditions can be adjusted to achieve a window of processing times that preserves the ultraflatness across the two materials. This window becomes very narrow if one of the materials easily oxidizes. Modifications in the final processing that could address this problem are changing the processing gas from oxygen to a purely ablative etching, or replacing the dry etch process with a wet etch of a thin sacrificial film. While we have not explored ablation so far, experiments with thin photoresist films showed that it can be difficult to achieve the very hydrophilic surfaces needed to achieve good nanosphere deposition. Photoresist films are also much thicker, which leads to reduced surface flatness. Other sacrificial layers that can be etched selectively, such as a thin metal film, are possible, as long as the epoxy is stable during the wet etch procedure. While nontransparent UNSL combinations can use extremely stable adhesives, optically transparent epoxies, needed for microscopic or spectroscopic applications, are less chemically resistant.

Figure 3.3: Characterization of dry etching step (a) Optical density of a glass slide coated with 8 nm carbon thickness as a function of etch time for different RIE powers. (b) SPR extinction spectra for different O₂ RIE times to remove the carbon layer on top of the UNSL sample: The SPR absorption peak shifts to the blue initially with the decreasing carbon thickness, i.e. increasing etch times, then between 120 s and 270 s there is no change, indicating that the carbon layer is completely removed, before finally the peak shifts red at 330 s indicating a slight etching of the gold areas. (c) SPR peak position as a function of etching time for Ag (squares, right axis) and Au (triangles, left axis). Representative AFM images of a carbon-coated UNSL surface (d), of a Ag-SiO₂ UNSL at 150 s (e), and 240 s (f) etch times, and of a Au-SiO₂ UNSL at 150 s (g), 270 s (h) etch times.

3.3.2 Selective functionalization of the nanopattern

Site-selective and chemoselective immobilization of proteins to functionalize solid surfaces and position target molecules are of interest for instance in proteomics research [40-43]. For the purpose of a sensor, chemical functionalization of an affinity ligand or other capture mechanism is required. Array type sensors should also define areas that represent a single element in the array and prevent lateral spreading and contamination during the spotting process. In addition, the smooth and flat surface of a solid substrate is very useful for selective protein immobilization for the purpose of easier image scanning and compatibility with standard instrumentation in proteomics. Suggestions for the potential usages of flat surface which can be used for site-selective surface functionalization and surface characterization was reported [18, 22, 28, 33].

In this thesis, we functionalize gold UNSL samples with thiols to selectively target the gold nanopattern and provide functionality. In this chapter we only show proof-of-principle that thiols selectively attach to the gold MNPs, and that the functionalization reaches a densely-packed self-assembled monolayer (SAM) of the expected 2 nm thickness. UNSL samples are stable in 3 mM ethanolic thiol solution for at least 48 h. The functionalization can be followed spectroscopically by UV-Vis spectroscopy and the adsorbate can be imaged with AFM. The ultraflatness of the sample allows us to directly image by AFM the change in height due to the functionalization (Figures 3.4a-b). In the low-topography state (Figure 3.4.a), we assigned the triangular Au areas of 1-2 nm height as no.(1)-(5) and no.(6) is assigned to the SiO₂ layer. The distance between no.(2) and no.(3) is approximately 400 nm which corresponds to the nanosphere size. Since hexadecanethiol (HDT) selectively binds to only gold nanopatterns, the surface topography after HDT modification is well defined as 4 nm associated with the nanopattern-HDT areas. The observed increase of 2 nm matches the expected height of a

densely packed monolayer of HDT. Additionally, the result shows that the final surface is no longer coated with carbon, and the thiol can bind selectively to the gold areas. The nanopattern of an Au/SiO₂ surface can also be selectively functionalized into micron-sized groups of thiolated nanopatterns by microcontact printing using a standard PDMS stamp. Again the thiol height is about 2 nm on the stamped areas (not shown), as long as the inking solution concentration is strongly reduced to 0.1 mM or less, and the sample is vigorously rinsed immediately after stamping in warm ethanol to remove thiols from the glass areas. Such visualization of the topography of thiol monolayers is impossible without ultraflat surfaces [18].

Figure 3.4: AFM images of the ultraflat nanopatterned surface before **(a)** and after **(b)** chemical modification of the gold patterned surface with HDT for 8 h. (a) no.(1)-no. (5) are assigned to Au-MNP, no.(6) is assigned to SiO₂ layer. The maximum height between no.(4) and no.(6) is about 2 nm before chemical modification. (b) The height is about 4 nm after functionalization. Height profiles are taken along the line in the respective images. **(c)** UV-Vis spectrum of a Au/SiO₂ UNSL surface in ethanol showing the gold nanoparticle LSPR peak shifting to the red by 2 nm after 3 h and by 25 nm after 8 h.

The chemical modification of the nanoislands is also confirmed by UV-Vis absorption spectroscopy. A peak shift to the red is expected for a change in refractive index from ethanol to a monolayer of thiol, which has a higher refractive index. Peak shifts of 2 nm and 25 nm to the red are observed as the incubation time with HDT is increased from 0 hours to 3 h and 8 h, respectively (Figure 3.4 c). It is interesting to note that the shift in the extinction peak is typical for a thiol adsorption and relatively small. This indicates that the technique is capable of preserving the anisotropic shape of the metal nanoparticles, in contrast to simple nanosphere lithography (NSL), which requires annealing the nanoparticles in methanol, leads to rounding of the corners, and to an associated large peak shift [3]. The spectroscopic measurements, showing a clearly distinguishable LSPR peak, also demonstrate the power of the new UNSL technique for creating functional elements, such as a SPR nanoparticle nanosensors, electrodes, or protein binding sites without any associated topography. This new technique preserves optically transparent materials, by embedding the functional components into the glass surface and by making use of the flexibility of the technique in choosing materials.

3.4 CONCLUSIONS

The introduction of a carbon low-adhesion layer together with an “unbreakable” template sandwich structure has allowed us to significantly improve the UNSL procedure by removing the template completely and reproducibly and creating nanopatterned surfaces that are ultraflat over cm^2 areas. We have shown here only gold and silver composites with SiO_2 , but many other material combinations can be envisioned. The ultraflatness allows for a thiol layer of 2 nm to be visualized for site-selective functionalization. The transparent nature of the UNSL samples demonstrated here can be used to perform SPR spectroscopy, which we have used to observe the processing steps. It also allows for the use of these particles as more sensitive SPR sensors that do not

require annealing, as we have been able to better preserve the triangular shape of the metal nanoparticles, unlike in NSL SPR sensors where the shape changes [44]. The ultraflat gold nanocomposite enables us experimentally to investigate the near field enhancement at the well-preserved sharp particle features. The bulk and local refractive index sensitivity is covered in chapter 4 and chapter 5. The template stripping technique demonstrated here could also be generalized to include prefabricated nanomaterials that can be embedded into a similarly template-stripped surface and so made to be topography free.

Chapter 4: Plasmonic optical sensor: Sensitivity of the bulk and local refractive index change and geometrical influences

4.1 INTRODUCTION

Noble metal nanoparticles (MNPs) have received great attention as bleach-resistant scattering labels, surface-enhanced raman scatterers, and potential nanoscale label-free optical biosensors [1-11]. Materials such as silver and gold have unique optical properties due to characteristic resonances, localized surface plasmon resonances (LSPRs) that lead to extinction bands in the visible range of the electromagnetic spectrum. These resonance extinctions are dependent strongly on the size, shape, and interparticle spacing; they depend also on the dielectric constant of the environment [2-4, 6, 11-14]. Therefore LSPR can be used to detect changes in the immediate vicinity of the MNPs by measuring the shift in the resonance position of the absorption spectrum. Because each MNP is its own sensor, very small amounts of protein are needed to induce a spectral change. Such sensing capability, although not as sensitive as phase-based detection schemes, is ideally suited for label-free detection in cases where often only small amounts of ligand are available such as in proteomics [3, 15, 16].

Spherical MNPs have been used as LSPR sensors successfully [17, 18]. However, non-spherical MNPs have higher sensitivity to changes in the environment [16, 19, 20]. Much work has been done on triangular-shaped MNPs, which are fabricated by nanosphere lithography (NSL)[1, 13]. It has been shown that such NSL-based LSPR sensors can achieve zeptomole sensitivity [10], and they have been used in applications such as detection of Alzheimer's disease [21]. However, stabilizing the sharp features in non-spherical MNPs is not trivial, and the changes in shape lead to large variations in the

resonance position. Chemical functionalization rounds the sharp features, which strongly shifts the resonance and significantly reduces the sensitivity [15].

As we have shown in the previous chapter, ultraflat nanosphere lithography (UNSL) can preserve sharp features by embedding MNPs into a surface of another material such as glass [22]. In this chapter we demonstrate an optimized UNSL-LSPR sensor, which has increased sensitivity over a gold NSL-LSPR sensor for bulk changes, and similar or better sensitivity to Ag NSL-LSPR sensors for modification at the surface.

4.2 EXPERIMENTAL METHODS

Materials: Polystyrene nanospheres of 500 nm, 400 nm, and 300 nm diameter were purchased from Interfacial Dynamics Corporation (Portland, OR). De-ionized water with a resistivity of at least 18.0 M Ω cm was used. Methanol and ethanol (Fisher Scientific, Houston, TX), and 1-Hexadecanethiol (Aldrich, Milwaukee, WI) were used as purchased. Optically transparent, low-viscosity epoxy, Epo-Tek #302-3M (Epoxy Technology Inc., Billerica, MA) or 20-3068 (Epoxies, Etc, Cranston, RI) was used for all bonding of surfaces. Plain microscope slides (1 mm thick, 2.2 x 4.4 cm²) (Erie Scientific, Portsmouth, NH), cover slips (0.13-0.16 mm thick, 2.2 x 2.2 cm²) and PVC slides (1 mm, 2.5x2.5 cm²) (all VWR) were used for substrates and templates. Tungsten vapor deposition boats and carbon crucibles and silicon dioxide (SiO₂) were purchased from Kurt J. Lesker Company (Clairton, PA). Silver (99.99%, 1-3 mm diameter) and gold (99.99%, 6.35 mm) were purchased from Alfa-Aesar (Ward Hill, MA), and carbon rods were purchased from Ted Pella Inc. (Redding, CA). Biotin-PEG-disulfide (Polypure, Oslo, Norway), Streptavidin (Sigma-Aldrich, St. Louis, MO).

Carbon-based UNSL gold MNPs preparation: To fabricate gold UNSL MNPs with preserved corners, the carbon-based template stripping method which is described in chapter 3 in detail was used. This technique allows us to make optically

transparent non-spherical gold MNPs partially embedded into an ultraflat surface of glass.

Conventional UNSL silver MNPs preparation: UNSL-fabricated silver MNPs were made by the conventional UNSL method [22] to avoid a silver oxide layer during the oxygen plasma etching processing step, as described in chapter 3.

Sample characterization: Samples were characterized by AFM (Asylum Research MFP 3D, Santa Barbara, CA) in contact mode under ambient conditions at scan speeds of 10-80 $\mu\text{m/s}$ using silicon nitride probes (NP-20, Veeco Metrology, Santa Barbara, CA). For height characterization and rms, the surface was measured over a $2 \times 2 \mu\text{m}^2$ area at scan speeds in the range of 1.5-4 $\mu\text{m/s}$. Ultraviolet-visible (UV-Vis) extinction spectra, measured in a Cary 5E UV-Vis-IR spectrophotometer (Varian), were used to follow the changes in the coating of the gold or silver particles.

Hexadecanethiol functionalization: After oxygen plasma dry etching to remove carbon from Au/SiO₂ UNSL surfaces, Au/SiO₂ UNSL samples were incubated in a 3 mM ethanolic solution of hexadecanethiol (HDT) (Aldrich) for up to 48 hours or as specified. Samples were rinsed in ethanol and dried under a stream of nitrogen.

Biotin-Streptavidin functionalization: After oxygen plasma dry etching gold UNSL samples were incubated in 1 mM ethanolic solution of Biotin-PEG-disulfide (MW:1539.9, Polypure) for two days. After incubating the gold MNPs with thiols, the samples were carefully rinsed in ethanol and dried under a stream of N₂ gas. Biotinylated gold samples were incubated in a 100 nM streptavidin solution in pH 7.5 20 mM phosphate buffered saline (PBS) for 3 hours. After the incubation, the streptavidin-biotin gold UNSL sample was rinsed in PBS buffer twice and extinction spectra were collected in PBS. Samples were rinsed afterwards in D.I. water twice, and completely dried under a stream of N₂ gas and UV-Vis spectra were re-measured in air.

4.3 RESULTS AND DISCUSSION

4.3.1 The bulk plasma and LSPR Absorption Spectroscopy

Before exploring localized surface plasmon resonances, it is good to understand the fundamental optical response of silver and gold. Silver and gold are very similar in not only lattice structure and lattice constants, but also the effective mass of the conduction electrons and density [2]. The major difference between silver and gold is the interband electron contribution in gold in the visible wavelength range, which induces the different optical properties of these noble metals. Silver and gold have about the same bulk plasmon frequency $\omega_p = \frac{de^2}{\epsilon_0 m_{eff}}$, which depends only on the free electron density, d , and the effective mass, m_{eff} , and therefore have the same associated plasma wavelength $\lambda_p \approx 138$ nm that determines the general frequency-dependent response of a metal to an electromagnetic field. Metals become almost transparent above the bulk plasma frequency range due to the inability of the free conduction electrons to follow the external electric field. The interband transition explains the natural colors of silver and gold. This is also experimentally shown in Figure 4.1.1. Silver and gold films of 60 nm thickness were prepared on a quartz slide, and the reflection and the absorption for these noble metal thin films were measured with reflection and transmission UV-Vis spectrometry. The onset of interband transitions for gold and silver can be seen as a transition from reflective to absorptive behavior and as a peak of the transmission. Silver is a metallic mirror due to reflecting almost all visible wavelengths above 400 nm. The reflectivity is greatly reduced at around 320 nm. Gold is yellowish red due to reflecting visible wavelengths above 600 nm and the reflectivity is significantly reduced at around 500 nm wavelength because of the interband transitions at 468 nm [23].

Figure 4.1.1: Reflectivity spectra for silver and gold thin films of 60 nm. A silver film reflects almost every visible wavelength above 400 nm. The reflectivity from the silver film is significantly reduced at 320 nm wavelength. The gold film reflects wavelengths above 600 nm, and the reflectivity is significantly reduced at 500 nm wavelength.

Figure 4.1.2: Absorption spectrum in transmission of silver and gold thin films of 60 nm thickness. The absorption of the silver film and the gold film are significantly reduced at 322 nm and 502 nm wavelength, respectively, due to the respective interband transitions.

While the absorption of a metal film is widely spread for wavelengths below the interband transition (Figure 4.1.2), the absorption of a non-spherical MNP exists only at a certain wavelength range with an extinction peak, $\lambda_{\max,SP}$, due to the localized surface plasmon resonance (Figure 4.1.3). Within the Drude approximation for a “free electron gas” of a metal, which applies well to Au and Ag at wavelengths larger than the interband transition, the LSPR wavelength for a small sphere can be expressed as [24]:

$$\lambda_{peak}^2 = \lambda_p^2 (\epsilon_\infty + 2\epsilon_m) \quad (4.1.1.)$$

with λ_{peak} the peak position of the LSPR, λ_p the bulk plasma wavelength (138 nm), ϵ_∞ the high frequency value of the dielectric constant of the metal (Ag \approx 4.9, Au \approx 13.2) contains all the interband transitions and ϵ_m the surrounding medium dielectric constant. Accordingly, the calculated LSPR peak for a sphere in air is at about 362 nm for Ag, and 538 nm for Au, which is relatively close to the real values. The sensitivity of the peak shift due to changes in the dielectric constant of the environment in this approximation is

$$S = \frac{\partial \lambda_{peak}}{\partial \epsilon_m} = \frac{\lambda_p}{\sqrt{\epsilon_\infty + 2\epsilon_m}} \quad (4.1.2)$$

which is higher for Ag than for Au due to the smaller infinity value of the dielectric constant.

This estimate does not apply for larger MNPs, as already larger spheres lead to higher sensitivity, and especially not to larger non-spherical particles. However, the sensitivity of the localized surface plasmon resonance for nanorods, can be shown to follow the empirical relation [25]

$$\frac{d\lambda_{\max,SP}}{dn_s} \propto \lambda_p R \quad (4.1.3)$$

where $\lambda_{\max,SP}$ is the extinction peak wavelength of the localized surface plasmon, n_s is the refractive index of the surrounding medium, and R is the aspect ratio (length/diameter) of the nanorod. The sensitivity of the surface plasmon peak position to

the refractive index change is, even for complicated particles, still determined by the bulk plasma wavelength and the MNP geometry. The higher sensitivity of Ag compared with Au for spherical shapes could also be expected to hold for more complex shapes. However, the quasi-static bulk sensitivity can be linearized [20]:

$$\frac{d\lambda_{\max SP}}{dn_s} = \frac{2}{n_s} \left(\lambda_{\max SP} + \frac{\varepsilon_x}{m} \right) \quad (4.1.4)$$

where the real part of the dielectric constant, ε_{real} , at frequencies below the interband transitions was linearized to:

$$\varepsilon_{real} = \varepsilon_x + m\lambda \quad (4.1.5)$$

Thus, the quasi-static bulk sensitivity is dependent on the real part of the gold or silver permittivity. Therefore the sensitivity is determined by the peak wavelength, and the slope m , and the intercept of the dispersion ε_x . Using Johnson and Christy data fits in the optical range below the interband transition gives

$$\varepsilon_{xAg}: 18.9, m_{Ag}: -0.058, \varepsilon_{xAg} / m_{Ag} = -326;$$

and

$$\varepsilon_{xAu}: 36.5, m_{Au}: -0.076, \varepsilon_{xAu} / m_{Au} = -480.$$

Given that the position of the peak for gold is also further to the red, a higher sensitivity of gold MNPs to the bulk environmental refractive index is expected.

The non-spherical MNPs of an UNSL sample show a resonance absorption peak at a specific wavelength $\lambda_{\max,SP}$. The spectra in Figure 4.1.3 show the particle-plasmon resonances of 30 nm thick and 93.2 nm long gold and silver UNSL MNPs with resonances at 794 nm and 508 nm, respectively. The peak positions of the particle resonances of the gold and silver particles are red shifted relative to those of the spherical particles, which is consistent with other reports [2]. This shift is larger for gold MNPs (~300 nm) than for silver MNPs (~100 nm).

Figure 4.1.3: Absorption spectrum of UNSL silver and gold particles of 30 nm thickness and 93.2 nm length. For the peak positions, silver has 580 nm, and gold 794 nm.

4.3.2 Role of the Geometry on the Properties of LSPR sensitivity in UNSL samples

It has been known that increasing the radius of spherical MNPs shifts the resonance peak position toward the red. In contrast, non-spherical MNPs have their resonance position red-shift if the particle becomes more non-symmetric. For the UNSL particles used here, the bisector and the particle thickness can be varied independently. To study the geometrical and material influences on the LSPR, different bisector lengths (117 nm and 93 nm) and different materials (gold and silver) as a function of the thickness were used.

The distance between MNPs also plays an important role, as the electromagnetic fields can couple. In our sample, which was made with 500 nm diameter spheres, the measured edge to edge distance between MNPs was $98 \text{ nm} \pm 9 \text{ nm}$ and $448 \text{ nm} \pm 10 \text{ nm}$ for the shortest and the longest distance, respectively. This distance is relatively large for near-field coupling and there should not be significant coupling between adjacent

particles [15, 33]. The long-range positional order is also probably not good enough to create far-field interference that would result in peak sharpening or broadening in the absorption spectrum [34].

As the thickness is reduced in both gold and silver type UNSL particles, the maximum peak position shifts to the red (Figure 4.2.1), which is consistent with the characteristics of conventional NSL MNPs [1]. When the bisector of gold MNPs is increased, the extinction peak position of the resonance is further red-shifted. DDA calculations have predicted that increasing the bisector of the triangular pyramids and decreasing its thickness shifts the resonance peak position to the red [12]. It is also found that gold shows larger red shifts of the resonance peak than silver for all thicknesses. This similar trend is also found in nanorods with high aspect ratio [25].

Figure 4.2.1: Position of the LSPR resonance as a function of MNP thickness for different bisector lengths in air and water as labeled for Ag and Au. As the particle thickness decreases, the sensitivity to the environmental changes increases in the two different gold particle bisector sizes. Below 30 nm thickness in gold particles, the sensitivity increases non-linearly. However, silver UNSL MNPs samples have no significant sensitivity changes over the whole thickness range.

4.3.3 The bulk refractive index sensitivity of LSPR in UNSL samples

As the bulk refractive index surrounding the MNPs is increased, the peak position is red shifted. Figure 4.3.1 shows an example of gold MNPs that are 20 nm thick and 117 nm long. Changing the bulk refractive index from air ($n = 1$), to water ($n = 1.33$), ethanol ($n = 1.36$), and oil ($n = 1.52$) shifts the resonance peak wavelength from 902 nm (in air), to 961 nm (in water), 971 nm (in ethanol), and 1011 nm (in oil), and the total red shift from air to oil is 109 nm. In comparison, one of the most sensitive, non-spherical silver MNPs produced with conventional NSL shows a 90 nm red shift from air to Pyridine solution ($n = 1.5$) [26]. This corresponds to a sensitivity of 1 nm peak change per 0.00555 refractive index unit (RIU) change, (180 nm/RIU for the silver NSL MNPs) compared to 1 nm per 0.00495 RIU, (202 nm/RIU for the gold UNSL MNPs).

Figure 4.3.1: Peak shifts in the absorption spectrum for gold UNSL MNPs. As the bulk refractive index at the gold UNSL MNPs is increased from (a) air ($n = 1$), to (b) water ($n = 1.33$), (c) ethanol ($n = 1.36$), and (d) oil ($n = 1.52$), the resonance peak positions are also red-shifted from 902 nm (in air), to 961 nm (in water), 971 nm (in ethanol), and 1011 nm (in oil).

The particle thickness not only influences the position of the LSPR peak, but also influences the bulk refractive index sensitivity, as already visible in Fig. 4.2.1. When the surrounding media is changed from air ($n = 1.0$) to water ($n = 1.33$), the resonance shifts to the red for all gold and silver particle thicknesses (Figure 4.2.1). However, the amount of the red shift of the resonance varies for different particle thicknesses at least for gold MNPs. Additionally, the sensitivity becomes larger for thinner gold MNPs. In 117 nm long gold MNPs, the average red shift in the particle thickness range from 65 nm to 30 nm is 60 nm (Figure 4.2.1). The average shift increases to 87 nm red shift below 30 nm thickness. The same is true for 93 nm long MNPs, which show an average peak shift of 33 nm from air to water in the particle thickness range from 77 nm to 35 nm, and an average of 60 nm red shift below 35 nm thickness. Thus, thinner particles in gold type UNSL have a higher sensitivity to changes in the surrounding environment compared to thicker particles.

It appears that there is a threshold for the metal particle thickness at around 30 nm, above which the sensitivity is constant, and below which the sensitivity strongly increases with decreasing thickness. (Figure 4.3.2). The high thickness sensitivity is 200 nm/RIU for 117 nm bisector gold type UNSL MNPs and 100 nm/RIU for the 93 nm bisector. Below this threshold, the sensitivity increases significantly to nearly 300 nm/RIU in the most sensitive gold MNPs measured here. Because the sensitivity of LSPR to the refractive index of the environment is higher in thinner particles, slight differences in the thickness of the particles result in large peak shifts. This creates tight constraints on the experimental conditions. In contrast, there is no threshold for the bulk refractive index sensitivity of silver UNSL MNPs (Figure 4.3.2). The sensitivity of silver type UNSL MNPs is relatively constant at 87 nm/RIU over the whole range of thickness variation.

Figure 4.3.2: Refractive index dependence of the peak position derived from Fig 4.2.1 as a function of particle thickness. The sensitivity of the LSPR rapidly increases in thinner particles below around 30 nm thickness in gold type UNSL MNPs in both (blue circle) 93 nm and (red square) 117 nm bisector sizes. The thinner gold MNPs have up to 3 nm peak shift /0.01 RIU (or 300 nm/RIU) sensitivity. However, for silver, the sensitivity is constant at 0.87 nm peak shift /0.01 RIU (or 87 nm/RIU) in all thickness ranges (green triangle).

In addition to the thickness dependence, there is also a close relationship between bisector length and the bulk refractive index sensitivity. As shown in Fig 4.3.3, the shift of the resonance peak changes linearly with the bulk refractive index, and the slope is determined by the bisector length of the triangular gold particle (Figure 4.3.3). As the bisector size is increased, the bulk sensitivity also increases. Increasing the bisector not only shifts the peak position to the red; it also enhances the bulk refractive index sensitivity. As the bisector is increased from 70 nm (sphere) to 117 nm (square), the sensitivity to changes in the bulk refractive index from air to oil ($n = 1.52$) increases the peak shift from 46 nm to 102 nm (Figure 4.3.3). These sensitivities can be described as a linear function of the refractive index by $\Delta\lambda = 191.2n - 194.1$, $\Delta\lambda = 139.8n - 140.9$, and

$\Delta\lambda = 83.1n - 86.30$, for 117 nm, 93 nm, and 70 nm bisector gold UNSL MNPs, respectively.

Figure 4.3.3: Linear peak shifts vs. the refractive index changes and bisector dependency in gold UNSL MNPs. As the bulk refractive index is increased, the peak shifts are increased. Even more, the slope of the peak shifts is increased as the bisector length of the particle is increased. The 117 nm bisector gold UNSL MNPs gives the most sensitive peak shifts: up to 102 nm (square) for the bulk refractive index change from 1 to 1.52. The 93 nm bisector length gold UNSL MNPs has 74 nm red shift in total (triangle). The 70 nm bisector length gold UNSL MNPs has 46 nm red shift in total (sphere). The sensitivity to the bulk refractive index is linear with $\Delta\lambda = 191.2n - 194.1$ (177 nm bisector) $\Delta\lambda = 139.8n - 140.9$ (93 nm bisector), and $\Delta\lambda = 83.1n - 86.30$ (70 nm bisector). The thickness for all samples is 26 nm.

Figure 4.3.4 is a summary of the geometric optimization, showing the bisector and the thickness dependence of the LSPR sensitivity to changes in the ambient refractive index. The best sensitivity achieved is 280 nm/RIU. A similar length dependence of the sensitivity has been shown for nanorods [27], with longer nanorods having a greater bulk refractive index sensitivity. As the rod length increases, not only is the LSPR sensitivity

much greater, but also the resonance peak positions shift to the IR range. The sensitivity to changes in the bulk refractive index does not follow Equation 4.1.4; it depends on the bisector more strongly than the difference in the maximum positions would predict. For example, the sensitivity of a 93 nm long, 26 nm thick gold MNP measures 43 nm for the peak shift from 752 nm in air to 795 nm in water. Equation 4.1.4, however, predicts the peak shift as 135 nm. The fit line $\Delta\lambda = 139.8n - 140.9$ in Figure 4.3.3 gives 45 nm of the peak shift. In the same way, the sensitivity of a 117 nm long, 29 nm thick gold MNP in Figure 4.2.1 has the peak shift as 55 nm (884 nm to 939 nm). However, Equation 4.1.4 anticipates the peak shift as 200 nm at 884 nm, while the fit line of $\Delta\lambda = 191.2n - 194.1$ in Figure 4.3.3 predicts 60 nm. Therefore, Equation 4.1.4, which states the peak position determines the sensitivity regardless of the geometrical shape, is not valid here. Since, Equation 4.1.4 assumes free-standing Au MNP, the substrate influence is at least one of the reasons for the discrepancy between Equation 4.1.4 and the measured results. The substrate leads to a red shift of the maximum absorption and therefore suggests a higher sensitivity than a free-standing particle, and this reduction in sensitivity due to the substrate was predicted by Lazarides's group [20].

Figure 4.3.4: Optimizing the bulk refractive index sensitivity by controlling bisector and thickness. Peak shift of the LSPR from air to water environment as a function of particle length (bisector) and thickness. By controlling bisector and thickness together, we can have the LSPR sensor most sensitive to the bulk refractive index changes with highly elongated thin gold type UNSL MNPs. The most sensitive gold type UNSL has 2.79 nm /0.01RIU (or 0.00358 RIU/nm) sensitivity. The gold particle thicknesses are 26 nm and 17 nm.

We have seen that the material also plays a role in the LSPR sensor sensitivity. Gold type UNSL MNPs have much higher sensitivity than silver type UNSL MNPs (Figure 4.3.2). In those experiments, it was not appropriate to use the new UNSL fabrication technique described in chapter 3, because the oxygen plasma etching would lead to thick silver oxide layers [28] which would reduce the sensitivity. Therefore the silver UNSL MNPs were made using the conventional UNSL fabrication method with mechanical mica stripping [22]. Although silver particles also show a red-shift of the resonance as the particle thickness decreases, there is no threshold or significant increase in the bulk refractive index sensitivity for the thinnest particles. In silver UNSL MNPs of 93 nm bisector length, an average red shift of only 28.8 nm was found between air and

water medium over the whole thickness range (Figure 4.2.1). The sensitivity is constant perhaps because of the constancy of the oxidation layer area at the surface of the silver regardless of the thickness variation in silver thickness inside the SiO_2 .

Because we found that the particle thickness and bisector play a role in the sensitivity of the gold UNSL sensor, but no dependence on thickness was found for the silver sensor (Figure 4.3.2), we questioned whether there is the bisector dependence of the sensitivity for the silver sensor. We deposited 300 nm, 400 nm, and 500 nm nanospheres on a mica substrate to create different bisector sizes. Although there is no significant thickness dependence for silver MNPs, the sensitivity depends on the bisector length (Figure 4.3.5). The question of why there is the bisector dependence in silver MNPs while there is no thickness dependence could be explained by the partial embedding of the silver particles and the silver oxidation at the exposed surface. The silver oxide layer thickness may occupy a large portion of the sensitivity range of the silver MNPs, but changing the bisector enhances the field around the MNPs and therefore increases the sensitivity. This is in contrast to conventional silver NSL MNPs, because in NSL, the MNP sides are also exposed to the ambient and contribute to the sensing area [1, 26].

Silver UNSL MNPs of 93 nm bisector shown before have an average sensitivity of 87 nm /RIU, but the data are very noisy. (Figure 4.3.2). In an experiment to compare different bisector lengths a thickness of 35 nm was used. The sensitivities were found to be 25 nm /RIU, 75 nm /RIU, and 122 nm /RIU for 70 nm, 93 nm, and 117 nm bisector length, respectively (Figure 4.3.5). These sensitivities are far lower than for gold MNPs.

Figure 4.3.5: Peak shift of the LSPR from air to ethanol environment as a function of particle length (bisector). The sensitivity of LSPR to refractive index changes is increased for longer particles in silver type UNSL MNPs. The silver particle thickness is 35 nm. These silver UNSL MNPs were made with the mechanical mica stripping method without any oxygen plasma etching. The sensitivity increase by increasing the bisector length gives 25 nm /RIU (or 0.04 RIU/nm), 75 nm /RIU (or 0.013 RIU/nm), and 122 nm /RIU (or 0.0082 RIU/nm) for 70 nm bisector length, 93 nm bisector length, and 117 nm bisector length, respectively.

Changing the bisector also changes the exposed area of the MNPs, and one could wonder whether the change in sensitivity is purely due to a change in surface area. First, the sensitivity for gold MNPs is linearly dependent on the bisector of the MNP with a slope described by $h = 0.4\Delta\lambda + 33.4$, where h is the bisector length (rectangle in Figure 4.3.6 A). At the same time the sensitivity is a linear function of the exposed triangular surface area. This surface area (circle in Figure 4.3.6 A) is described by $A_{UNSL} = 46.7\Delta\lambda - 1207.3$, where A_{UNSL} is the triangular surface area. Because the bisector h and the area A_{UNSL} are geometrically linked by:

$$A_{UNSL} = \frac{1}{\sqrt{3}}h^2 \quad (4.3.1)$$

a nonlinear dependence of the sensitivity would be expected for one of the parameters if geometry is the determining parameter. We checked whether doubling the area causes twice the sensitivity. The relative sensitivity as a function of relative bisector length and relative triangular area are plotted for clear comparison in Figure 4.3.6 B. The relative sensitivity, $\Delta\lambda_r$, is a linear function of the relative bisector, h_r , with $\Delta\lambda_r = h_r$ and the relative exposed area, $A_{UNSL,r}$, with $\Delta\lambda_r = 0.7A_{UNSL,r} + 0.3$. The direct proportionality with the bisector is similar to equation 4.1.3 for a rod, where the aspect ratio determined the sensitivity, and a simple area dependence can be excluded.

An additional possibility of a purely area-related influence is the change in area that is exposed relative to the area that is covered by the glass, which would contribute a constant component to the environment the MNPs experience. With b the thickness of the MNPs (see Figure 4.3.6), the exposed area relative to the total surface area is:

$$A_{UNSLrel} = \frac{1}{2 + 6\frac{b}{h}} \quad (4.3.2)$$

For 26 nm MNPs and bisectors of 70 nm, 93 nm, and 117 nm, this ratio increases with bisector length far too slowly to account for the observed increase in sensitivity. Although there is an area and bisector influence to the sensitivity, we can conclude that the sensitivity increase is not determined by the additional area provided by larger MNPs. Instead, it is most likely the result of the field distribution around the MNPs at the resonance.

Figure 4.3.6: Contribution of the bisector and the exposed area in the bulk refractive index sensitivity. (A) Linear relationship between bisector length and the bulk refractive index sensitivity. As the bisector length is increased, the bulk sensitivity also increases. The bisector length (rectangle) can be fit to a line as a function of the sensitivity described by $h = 0.4\Delta\lambda + 33.4$. The exposed area also plays a role in the sensitivity. The triangular area (circle) can be fit to a line as a function of the sensitivity described by $A_{UNSL} = 46.7\Delta\lambda - 1207.3$. (B) The relationship between the relative bisector length and the relative exposed surface area and the bulk refractive index sensitivity. There are both bisector and area linear dependencies to the sensitivity. These data can be fit to a line described by $\Delta\lambda_r = h_r$ for the relative bisector length (square and blue fit) and $\Delta\lambda_r = 0.7A_{UNSL,r} + 0.3$ for the relative triangular area (circle and red fit).

In summary, there is a significant influence of the particle geometry and the material on the position of the LSPR resonance and the sensitivity to changes in the ambient bulk refractive index. The sensitivity is a linear function of the bulk refractive index, and of the MNP thickness and bisector length. Silver UNSL MNPs are less sensitive than gold MNPs, at least in part due to the formation of an oxide layer.

4.3.4 The local refractive index sensitivity of LSPR in UNSL samples

While the sensitivity to the refractive index of the bulk medium is important for the stability of a sensor and its background signal, most affinity binding takes place within the 10-15 nm closest to the surface of the MNP. There local field distributions and enhancements play a major role in determining the sensitivity.

Figure 4.4.1 shows the UV-Vis extinction spectrum for gold UNSL MNPs in air before and after 1-hexadecanethiol, (1-HDT) incubation. The gold particle thickness used here is 30 nm and the bisector length is 93 nm. As the 1-HDT incubation time increases, the LSPR peak position $\lambda_{\max,SP}$ shifts to the red (Figure 4.4.1) by 6 nm from 860 nm to 866 nm after 3 hours and another 19 nm from 866 nm to 885 nm after 8 hours (total 25 nm red-shift). A red shift can be expected due to the dielectric environment change from air ($n = 1$) to the SAM ($\varepsilon = 2.1$) in the first 2 nm around the particle.

The red shift caused by an increasing 1-HDT incubation time can be explained by defining an effective refractive index n_{eff} that takes the local field profile into account [29]

$$n_{eff} = \frac{2}{L} \int_0^\infty n(z) \exp(-2z/L) dz \quad (4.4.1)$$

where $n(z)$ is the area-averaged refractive index at distance z from the metal surface, and L the decay length of the evanescent field. This equation has been used in propagating SPR sensors for determining the response of adsorbate layers, but it has also been adopted for LSPR sensors [16]. The effective refractive index change can be formulated by

$$\Delta n_{eff} = \frac{2d}{L} (n_a - n_s) \quad (4.4.2)$$

where d is the effective thickness of the thin film, n_a is the refractive index of uniformly packed pure adsorbate on the surface, and n_s the refractive index of solvent or medium.

Alternatively, before a complete thin film has formed on the surface, the SAM thin film is porous and interspersed with solvent, which is ethanol in this experiment. Thus, the effective refractive index change must be expressed by the effective thickness, d , of the thin film. The effective thickness can be formulated again by

$$d = \frac{L}{2} \left(\frac{\Delta n_{eff}}{n_a - n_s} \right) \quad (4.4.3)$$

Once the effective thickness is calculated, then the surface coverage, C , can also be calculated from the effective thickness by

$$C(\text{molecules} / \text{cm}^2) = d(\text{cm}) \times N(\text{molecules} / \text{cm}^3) \quad (4.4.4)$$

where $N = \frac{\rho}{M_w} N_A$ is the bulk number density, ρ is the bulk mass density of the pure saturated SAM layer, M_w is the molecular weight of the SAM, and N_A is Avogadro's number. Therefore, the LSPR response due to an effective refractive index change can be understood as the SAM coverage on the MNP surfaces. Thus Figure 4.4.1 can be interpreted as a surface coverage increase with increasing incubation time, and the red shift in the resonance peak is due to an increase of the effective refractive index.

Figure 4.4.1: Absorption spectrum of gold UNSL MNPs. As 3 mM of hexadecanethiol (1-HDT) is functionalized on the gold MNPs, there are red-shifts from before 1-HDT incubation which is at 860 nm (red solid line) to 866 nm (green dashed line) for 3 hours and 885 nm (blue dotted line) for 8 hours. Particle bisector size = 93 nm, Particle thickness in SiO_2 = 35 nm. This is reproduced from Figure 3.4 in chapter 3.

To study the sensor sensitivity to local refractive index changes caused by the adsorbed analyte, biotin-streptavidin layers were used with UNSL-fabricated gold MNPs. UV-Vis extinction spectroscopy and AFM scanning were used to confirm the multilayer incubation process. Figure 4.4.2 shows AFM images before (Figure 4.4.2 A) and after incubation with a biotinylated thiol and streptavidin (SA) on UNSL-fabricated gold MNPs, with Figure 4.4.2 B showing an average height of 2-3 nm averaged over several line scan data (maximum height is up to 6 nm), while a densely packed SA layer is 4-6 nm thick [30]. The average 2 nm of height is due to a loosely packed SA layer.

Figure 4.4.2: Representative AFM images of UNSL-fabricated gold MNPs for chemical modification. (A) Bare gold MNPs before chemical modification. (B) After incubation with 100 nM streptavidin for 3 hours for the biotinylated gold MNPs. Particle bisector = 117 nm. Particle thickness = 20 nm. The SA-biotin thickness is 2 nm on average due to a loosely packed SA layer. Gray scale is from -2 nm to 2 nm. Scan rate = 2 Hz in tapping mode.

Results corresponding to Figure 4.4.2 are shown in Figure 4.4.3 as the LSPR $\lambda_{\max SP}$ positions as a function of the local refractive index change due to adsorption of

biotin and SA. When the adsorbate layers, 1 mM of the biotin-PEG-thiol and 100 nM of the streptavidin-biotin-thiol layer on the gold MNP surface, is measured in air, the resonance peak position shifts to the red (Figure 4.4.3 A). This trend is also found in higher bulk dielectric environments such as water or PBS buffer (Figure 4.4.3 B), but the shift is much smaller. The LSPR peak position $\lambda_{\max SP}$ after biotin-PEG-disulfide attachment on the gold MNPs was measured to be 1003 nm ($\Delta\lambda = 29$ nm) in air, and 1064 nm ($\Delta\lambda = 8$ nm) in water. The LSPR peak position $\lambda_{\max SP}$ after streptavidin binding to the biotinylated gold MNPs is 1010 nm ($\Delta\lambda = 7$ nm) in air, and 1067 nm ($\Delta\lambda = 3$ nm) in PBS buffer.

Figure 4.4.3: Local refractive index dependency for the resonance peak positions. (A) Local refractive index influence in air for 1 mM biotin and for 100 nM SA. The peak shift from bare gold to biotin layer is $\Delta\lambda = 29$ nm and the peak shift from biotin to streptavidin layer is $\Delta\lambda = 8$ nm. (B) Same adsorbate layers with (A) in higher dielectric environment. The peak shift from bare gold to biotin layer is $\Delta\lambda = 7$ nm in water and the peak shift from biotin to streptavidin layer is $\Delta\lambda = 3$ in PBS buffer environment. The refractive index of the PBS buffer is 1.33. Particle sizes are same as in Figure 4.4.2.

The adsorbate-induced local refractive index sensitivity is reduced by the higher bulk refractive index of water ($n = 1.33$) compared to air ($n = 1$) (Figure 4.4.4). This can be explained by the relative dielectric constant, $\epsilon_{\text{adsorbate, rel}}$, of the adsorbate layer, $\epsilon_{\text{adsorbate}}$, surrounded by a medium of dielectric constant, ϵ_{medium} ,

$$\epsilon_{\text{adsorbate, rel}} = \frac{\epsilon_{\text{adsorbate}}}{\epsilon_{\text{medium}}} \quad (4.4.5)$$

The relative dielectric constant for the adsorbate in aqueous environment, assuming for the adsorbate $\epsilon_{\text{adsorbate}} = 2.25$, is therefore strongly reduced to $\epsilon_{\text{adsorbate, rel}} = 1.69$, or the refractive index is reduced from 1.5 in air to 1.3 in buffer.

Figure 4.4.4: Bulk refractive index influences the local refractive index sensitivity. The sensitivity relative to the bare surface to local refractive index changes at two steps of adding adsorbate layers (1 mM biotin, and 100 nM streptavidin) is shown. The relative local refractive index sensitivity is reduced by the higher bulk refractive index of water ($n = 1.33$). Particle sizes are the same as in Figure 4.4.2.

However, a fast drop in sensitivity (Equ. 4.4.1) makes this influence less pronounced, and non-spherical MNPs with high, but short-range fields can therefore increase the sensitivity. Indeed, already the biotin and streptavidin layers reduce the sensitivity to the medium by more than 30 %, as can be seen from differences between air and buffer resonance peak positions (Fig. 4.4.5). This result agrees with experiments for silver NSL MNPs with 100 nm bisector size and 50 nm thickness, where the sensitivity to the bulk refractive index drops (from methanol $n = 1.3288$ to benzene $n = 1.5011$) from 196 nm/RIU before to 159 nm/RIU after hexadecanethiol modification [15].

Figure 4.4.5: Multilayer adsorbate influences on the bulk refractive index sensitivity. The resonance peak position of UNSL-fabricated gold MNPs with adsorbate layers was measured in air and water (or PBS buffer). Adding adsorbate layers to the gold MNPs significantly reduces the bulk refractive index sensitivity. Bare gold MNPs have an 82.3 nm peak shift from air ($n = 1$) to water ($n = 1.33$). Biotinylated gold MNPs have a 61.3 nm peak shift, and biotin-streptavidin gold MNPs have a 56.6 nm peak shift. Particle sizes are same as in Figure 4.4.2.

In summary, the bulk refractive index sensitivity of the MNP sensor reduces the adsorbate sensitivity, but local field engineering should be able to tailor the decay length to reduce the bulk influence. Others have also shown that the enhanced near fields can play an important role in the sensitivity of MNP sensors [15].

4.3.5 Comparison of the refractive index sensitivity in unit sensing area in NSL and UNSL

There are differences in the areas exposed to the ambient environment for NSL-fabricated samples and UNSL-fabricated samples. UNSL-fabricated samples have only one exposed surface used in sensing. However, NSL-fabricated samples have 4 exposed surfaces. Understanding these different areas used in plasmonic sensing is essential. The area of UNSL and NSL surface (Figure 4.5.1) is

$$A_{UNSL} = \frac{1}{2}ah = \frac{\sqrt{3}}{4}a^2 \quad \text{and} \quad A_{NSL} = \frac{1}{2}ah + 3ab = \frac{\sqrt{3}}{4}a^2 + 3ab \quad (4.5.1)$$

where a is the side of the equilateral triangle, b the thickness (out of plane) of the triangular pyramid, and h is the height of the triangle. The triangle is assumed to be equilateral for simplicity. Similarly, the relative exposed areas for the two fabrication techniques is

$$A_{UNSL,NSL,ratio} = \frac{0.5h}{0.5h + 3b} \quad (4.5.2)$$

The main difference in the total area between NSL and UNSL is the additional side surface $3ab$. The question therefore is how large is the contribution from the out of plane thickness b , and can it be used to improve the sensitivity of the LSPR sensor?

Figure 4.5.1: Comparison of the area of a NSL-fabricated and an UNSL-fabricated sample for sensing capability. The triangular area for NSL and UNSL samples is calculated for an equilateral triangle for easier calculation. h is the height of the triangle. b is the NSL thickness which is exposed to the environment. UNSL has no thickness exposed to the environment.

It has been shown that, similar to UNSL-fabricated gold MNPs, NSL-fabricated silver MNPs have an enhanced sensitivity with reduced out-of-plane thickness, b [16, 26]. In contrast, rounded ellipsoidal particles significantly gain in sensitivity by increasing the exposed area and therefore have higher sensitivity if b is increased [26].

We compare the sensitivity of NSL and UNSL-fabricated (Figure 4.3.5) silver MNPs with bisector length $h = 93$ nm and thickness $b = 28$ nm. The bulk refractive index

sensitivity for the most sensitive silver NSL MNPs is 200 nm/RIU [26], compared to 75 nm/RIU for silver UNSL MNPs (Figure 4.3.5, $h = 93$ nm), or 38 % of the NSL sensitivity. Therefore the sensitivity per unit area for silver NSL MNPs is $1.42 \times 10^{-2} \text{ nm/RIU/nm}^2$ and for silver UNSL MNPs of the same size $1.48 \times 10^{-2} \text{ nm/RIU/nm}^2$, while for the most sensitive silver UNSL MNPs ($h = 117$ nm) it is $1.55 \times 10^{-2} \text{ nm/RIU/nm}^2$. As the ratio of the exposed areas of UNSL and NSL is 36 % and the sensitivity of the UNSL MNPs is 38 %, the sensitivity appears to be determined by the relative exposed areas and NSL has an advantage over UNSL. However, this advantage holds only for the most insensitive UNSL MNPs, which appear to not benefit much from reducing the out-of-plane thickness b .

Because our Ag UNSL samples show very low sensitivity, we compared the Au UNSL samples to NSL results. For NSL the sensitivity for gold MNPs is reduced to less than 60 % of the sensitivity of the silver NSL MNPs. Comparing the gold UNSL MNPs of the same bisector length of $h = 93$ nm and thickness $b = 17$ nm (Figure 4.3.4) to the silver NSL MNPs, the UNSL MNP sensitivity, which is 197 nm/RIU, is improved to 98.5 % of silver NSL MNPs. Additionally, with optimized geometry, sensitivities of close to 300 nm/RIU for gold UNSL MNPs can be achieved by reducing the out-of-plane thickness, as has been suggested for NSL too [26]. However, NSL MNPs that are very thin easily become ellipsoidal and lose this advantage [26], and often much thicker NSL MNPs are used ($b = 50 \sim 75$ nm). We therefore conclude that the exposed surface area plays a role for silver, possibly because of the surface oxidation, but appears not important for gold.

We also compare the local refractive index sensitivity in UNSL and NSL samples. In section 4.3.4, we have explored the local refractive index sensitivity with short range distance dependence of the UNSL-fabricated LSPR sensor. NSL sensors have been

experimentally used to understand that the enhanced near fields play an important role in the resonance sensitivity [15].

To compare the area contribution in the local refractive index sensitivity, data from Figure 4.4.1 was used for gold UNSL MNPs. All NSL data used here are taken from reference [15]. Gold and silver NSL area data are for bisector $h = 100$ nm and thickness $b = 75$ nm. Gold and silver NSL MNPs were incubated in 1mM HDT for 24 hours (Figure 4.5.2 A, D) and the thiol layer produced 38.1 nm (silver) and 13.8 nm (gold) peak shifts to the red. Gold UNSL MNPs with $h = 93$ nm and $b = 35$ nm produced 25 nm (8 h in 3 mM HDT) and with $h = 117$ nm and $b = 20$ nm produced 30 nm (24 h in 1 mM HDT) of the peak shift (Figure 4.5.2 B).

Because the thiol packs more tightly, and is upright on silver as compared to on gold, where it assumes a 30° angle, the thickness of the layer and the refractive index may be slightly different. We assume constant refractive index, but compensate for the slightly different thickness. The slope, taken as the short-range sensitivity near the particles (Figure 4.5.2), is the largest for silver NSL MNPs with 14.6 nm shift per nm thickness (blue solid line in Figure 4.5.2 A), closely followed by gold UNSL MNPs with $h = 117$ nm and 24 h incubation with 13.7 nm shift / nm thickness (red solid line in Figure 4.5.2 B). Gold UNSL MNPs with $h = 93$ nm and 8 h incubation produce 11.6 nm shift / nm thickness (red dotted line in Figure 4.5.2 C), while gold NSL MNPs are the least sensitive with 6.4 nm shift / nm thickness (blue dash-dotted line in Figure 4.5.2 D). Although the analyzed gold UNSL MNPs can be made more sensitive by increasing the bisector length, at least a similar near-range sensitivity can be achieved.

Figure 4.5.2: Comparison of the local refractive index sensitivity with hexadecanethiol (HDT) layer on NPs. (a) NSL-fabricated silver MNPs ($h = 100$, $b = 75.1$ nm) has 38 nm peak shift (blue solid line) with the sensitivity slope 14.6 [peak shift(nm)/ nm thickness]. (b) UNSL-fabricated gold MNPs ($h = 117$ nm, $b = 20$ nm) has 30 nm peak shift (red solid line) with the sensitivity slope 13.7 [peak shift(nm)/ nm thickness]. UNSL-fabricated gold was incubated (red solid line) with 1 mM HDT for 24 hours. (c) UNSL-fabricated gold MNPs ($h = 93$ nm, $b = 35$ nm) has 25 nm peak shift (red dotted line) with the sensitivity slope 11.6 [peak shift(nm)/ nm thickness]. UNSL-fabricated gold ($h = 93$, $b = 35$ nm) was incubated (red dotted line) with 3 mM HDT for 8 hours. (d) NSL-fabricated gold MNPs ($h = 100$, $b = 75.1$ nm) has 13.8 nm peak shift (blue dash-dotted line) with the sensitivity slope 6.4 [peak shift(nm)/ nm thickness]. NSL samples were incubated with 1 mM HDT for 24 hour [15].

4.4 CONCLUSIONS

In the quasi-static approximation, the bulk plasma wavelength determines the LSPR position and the LSPR position in turn determines the LSPR sensitivity to adsorbed layers or bulk refractive index changes. The resonance extinction peak position is bisector length, thickness, and material dependent in non-spherical MNPs. The peak position is also a linear function of the bulk refractive index, and the slope or sensitivity is a linear function of bisector length, and can be improved by reducing the thickness. Thinner and longer, i.e. more non-spherical, particles have higher sensitivity to the bulk environmental changes. The threshold in the LSPR sensitivity as a function of the

thickness of the UNSL MNP may be explained by confinement effects, which play a significant role under 30 nm. Thus, understanding the geometrical influences on the bulk refractive index sensitivity and optimizing the non-spherical MNP geometry are crucial steps to make a sensitive sensor.

Functionalizing UNSL-fabricated gold MNPs with HDT and biotin-streptavidin was used to understand the local refractive index sensitivity. The resonance peak positions are dependent on the effective coverage of the HDT SAM or biotin-thiol and streptavidin. On the other hand, we found that the bulk refractive index also influences the local sensitivity to refractive index changes. A higher bulk refractive index reduces the local refractive index sensitivity by lowering the effective dielectric constant of the absorbate in the surrounding medium. These adsorbate layers reduce the sensitivity to the bulk refractive index.

When non-spherical MNPs are embedded in SiO_2 as with UNSL, the optical properties are changed, especially in silver. Unlike with NSL, there is no significant thickness dependency in bulk refractive index sensitivity in UNSL-fabricated silver MNPs, although the sensitivity can be increased by increasing the bisector. That may be explained by the silver oxidation on the exposed surface area.

The bulk refractive index sensitivity is also affected by the material. It was shown that UNSL-fabricated gold MNPs have a much higher sensitivity than silver MNPs when thickness and bisector length have been optimized.

The sensitivity of NSL and UNSL were compared for both the bulk refractive index and the local refractive index. NSL-fabricated gold MNPs always have a lower sensitivity than silver NSL MNPs. The exposed area in UNSL samples is significantly smaller than that of NSL-fabricated silver samples, and the sensitivity appears to be determined by the relative exposed areas and NSL has an advantage over UNSL.

However, reducing the out-of-plane thickness in UNSL samples which significantly enhances the sensitivity overcomes this drawback. This solution is not valid in NSL samples due to losing the sharpness at the corners and the edges.

LSPR sensors are not only limited to NSL-fabricated MNP sensors, but also include other shapes such as nanocubes [19], triangular nanoprisms [31], nanorods [25] and nanocrescents [32]. The most sensitive UNSL-fabricated Au MNP sensors has a bulk refractive index sensitivity of close to 300 nm/RIU with 117 nm bisector length. A single silver nanocube has 98 nm/RIU sensitivity to bulk refractive index changes, while a single silver triangular nanoprism has 205 nm/RIU, and averaging over several particles may even decrease the sensitivity. A gold nanocrescent with a diameter of 125 nm and a resonance in the near-IR has 368 nm/RIU, but it is not clear how well the crescents would survive chemical functionalization [31]. Therefore, our UNSL-Au MNP has a better sensitivity compared to most MNP LSPR sensors. This sensitivity may be even increased further by increasing the bisector to make highly elongated shapes. This trend is in agreement with modeling for nanorods that predict even higher sensitivities under optimized diameter and aspect ratio conditions. DDA calculations for highly elongated nanorods have predicted the sensitivity to increase up to 491.4 nm/RIU [25].

It is also shown that increasing the exposed surface area is not effective, but using gold material with UNSL and increasing the bisector length and lowering the thickness, in a trend resembling the nanorod dependency on the aspect ratio, is much more effective in achieving better plasmonic sensitivity.

Chapter 5: Computational modeling for near-field and far-field investigations of non-spherical triangular particles

5.1 INTRODUCTION

The classical electromagnetic theory of spherical particles has been well known for a century with Maxwell's equations and Mie theory [1-3]. The unique optical, electrical, and chemical properties of noble metals such as silver or gold have been attractive for use in biochemical sensing and detection with localized surface plasmon resonances [4-6]. Mie theory explains clearly the size dependence of the localized surface plasmon resonance in the spherical MNPs [1].

Recently with advanced nanotechnology, more complicated non-spherical MNPs have been made and characterized by chemical synthesis [7-9] and lithographic techniques [10-12]. However, Mie theory can't explain the electromagnetic field for complicated non-spherical MNPs with sharp features. Many experimental results have shown that the LSPR of the non-spherical MNPs is very dependent on size [10, 13-15], shape [13, 14, 16], dielectric environment [13, 17, 18], and material [19, 20]. Many theoretical tools such as the discrete dipole approximation (DDA) [17, 21, 22], finite difference time domain (FDTD) [23-25], finite element method (FEM) [26, 27], and T-matrix method [3] have been used to understand the unique properties of the LSPR of non-spherical MNPs.

Among these methods, both FEM and FDTD initially have unknown electric and magnetic fields at the finite elements, or mesh nodes. To limit the number of unknown fields at mesh nodes, FEM and FDTD must be implemented in a finite computational domain due to finite computational accuracy, time, and resources. As the computational

technology has advanced, FDTD and FEM have become powerful space- and time-dependent calculation methods for the electromagnetic fields around non-spherical MNPs. The space and time iteration method both in FDTD and FEM provides convenient graphic user interfaces with modern powerful computational resources. FEMLAB 3.3a® as FEM and XFDTD® as FDTD tool were used here to understand the LSPR characteristics of the non-spherical MNPs in the near-field and the far-field and the influence of the substrate that the MNPs are in contact with in NSL and in UNSL. The corresponding experimental results are covered in chapter 4 in this dissertation. For this calculation, an Intel® Xeon® Quad core 64 bit CPU and 8GB memory were used.

5.2 THEORETICAL METHODS

Numerical calculations using the finite-element package FEMLAB and the finite-difference-time-domain package XFDTD require a virtual boundary to limit the size of computational space, which is limited by computer resources. One way to define the computational boundary is to create absorbing boundary conditions (ABCs). The ABCs keep the scattering or total field calculations accurate and prevent unwanted spurious reflections. This is most effectively achieved by the perfectly matched layer (PML) method, the most popular condition to create ABCs in FEM and FDTD [25, 28]. If a wave is propagating in medium A and it impinges on medium B, the reflection Γ is determined by the impedance difference of the two media as

$$\Gamma = \frac{\eta_A - \eta_B}{\eta_A + \eta_B} \quad (5.1.1)$$

where $\eta_A = \sqrt{\frac{\mu_A}{\varepsilon_A}}$ and $\eta_B = \sqrt{\frac{\mu_B}{\varepsilon_B}}$ are the intrinsic impedances with magnetic permeability μ and electric permittivity ε of the medium A and B, respectively.

The complex permittivity and the complex permeability can be described as $\epsilon^* = \epsilon + j \frac{\sigma_\epsilon}{\omega}$, $\mu^* = \mu + j \frac{\sigma_\mu}{\omega}$ [29], with the electric conductivity σ_ϵ , the magnetic loss σ_μ , and angular frequency ω . Thus, the intrinsic impedance in the medium B is

$$\text{rewritten as } \eta_B = \sqrt{\frac{\mu_B (1 + j \frac{\sigma_\mu}{\omega \mu_B})}{\epsilon_B (1 + j \frac{\sigma_\epsilon}{\omega \epsilon_B})}}.$$

If we set an impedance matching condition as

$$\epsilon_A = \epsilon_B \quad (5.1.2)$$

$$\mu_A = \mu_B \quad (5.1.3)$$

$$\frac{\sigma_\mu}{\mu_B} = \frac{\sigma_\epsilon}{\epsilon_B} \quad (5.1.4)$$

This yields the conditions $\eta_A = \eta_B$ and $\Gamma = \frac{\eta_A - \eta_B}{\eta_A + \eta_B} = 0$, and a reflection-free

interface between the medium A and the medium B for the impinging wave, regardless of propagation direction or wavelength, is achieved. As σ_ϵ and σ_μ in the medium B increase, η_B is equal to η_A because of the impedance matching condition.

In a PML medium, the electric conductivity is assumed as an m-power parabolic profile as [28]

$$\sigma_\epsilon = \sigma_{\max} \left(\frac{x - x_0}{d} \right)^m \quad (5.1.5)$$

where x is the distance from the beginning of the PML, d is the thickness of the PML medium, and $m = 2$ is most often used.

Figure 5.1.1 : The electric conductivity continuity between computational region and PML region. The conductivity is expressed as $\sigma_\epsilon = \sigma_{\max} \left(\frac{x - x_0}{d} \right)^m$. As the conductivity increases, the reflection Γ at the interface is reduced, as shown by equation 5.1.4 and equation 5.1.1.

A material parameter like the relative permittivity, ϵ_r , generally is dispersive and varies as a function of frequency. The real part of the complex permittivity is negative for metals. FDTD requires time responses of the electric field and the magnetic field in the dispersive medium. However, time domain calculations like FDTD for Maxwell's equations are unstable when using negative values in a complex permittivity. One alternative to avoid negative permittivity for use in FDTD is to work in Fourier space with a frequency dependent dielectric constant and conductivity. Introducing a frequency-dependent conductivity into Maxwell's equation allows accurate wide frequency computation of the transient electromagnetic field with FDTD for negative-index materials in the frequency domain [23, 24, 30].

The Fourier transform of the complex permittivity of a free electron gas metal is described by the standard Drude equation as [31]

$$\varepsilon^*(\omega) = \varepsilon' - j\varepsilon'' = \varepsilon_\infty + \frac{\varepsilon_s - \varepsilon_\infty}{1 + j\omega\tau_0} + \frac{\sigma}{j\omega\varepsilon_0} = \varepsilon_\infty + \chi(\omega) + \frac{\sigma}{j\omega\varepsilon_0} \quad (5.1.1)$$

where ε_s is the static permittivity at zero frequency, ε_∞ is the infinite frequency permittivity, τ_0 is the relaxation time, ε_0 is the permittivity in free space, σ is conductivity, and $\chi(\omega)$ is the frequency domain susceptibility. Gold and silver, however, are not perfect Drude metals due to their interband transitions, and, for the frequency range of interest, the complex permittivity is therefore approximated by effective parameters of the Drude model.

The following Drude parameters were used in this dissertation to numerically fit the empirical real and imaginary parts of the gold permittivity taken from Johnson-Christy's experimental data [32]: $\varepsilon_\infty = 8.175230$, $\varepsilon_s = -5.787620\text{e}+03$, $\tau_0 = 5.623413\text{e}-15$, and $\sigma = 9.172759\text{e}+06$. The fit for the real part of the permittivity (Figure 5.1.2 A) is very close for the experimental data for wavelengths between 600 nm (500 THz) and 1.9 μm (150 THz). The real part of the permittivity is important as it determines the resonance peak position. The imaginary curve fit (Figure 5.1.2 B) is not as close for the same experimental data range, but it affects only the peak width, and is therefore acceptable in our numerical simulation. The numerical fit for the imaginary part can be improved by using the Drude-Lorentz equation [33], but the XFDTD program has no compatibility with this equation yet.

Figure 5.1.2 : Real (A) and imaginary parts (B) of permittivity of gold and the associated fit curves. Blue lines are experimental data [32] and the best fit curves (red lines) were obtained from a Drude model for wavelengths from 600 nm to 1.9 μm (from 1.5e2 THz to 5e2 THz) with the following parameters $\epsilon_\infty = 8.175230$, $\epsilon_s = -5.787620\text{e} + 03$, $\tau_0 = 5.623413\text{e}-15$, and $\sigma = 9.172759\text{e}+06$.

Because most measurements are performed with UV-Vis spectroscopy, the scattering or extinction spectra for the far-field need to be calculated to allow for comparisons between model and experiment. Using the near-field data obtained from FDTD and FEM calculations, it is possible to perform a near-to-far-field transformation. This means there is no need to extend the FDTD or FEM grid to the far-field range. It can be shown that the far-field calculation is determined by the interference of the tangential components of the electric and magnetic fields on a virtual surface completely surrounding the scattering object. As mentioned earlier in chapter 2, the transformation that relates the local fields on the sphere to the far field at the point p is:

$$E_p = \frac{jk_o}{4\pi} r_o \times \int [n \times E - \eta_o r_o \times (n \times H)] \exp(jk_o r \cdot r_o) dS \quad (2.4.5)$$

where r_o is the unit vector pointing from the origin to the field point p, n is the unit normal to the surface S, η_o is the free space impedance, k_o is the free space wave number, r is the radius vector of the surface S. The far field point p is taken normally at 1 m with spherical coordinate position θ and ϕ . The far field intensity pattern is given by $|E_p|^2$.

5.3 RESULTS AND DISCUSSION

5.3.1 Rayleigh scattering for a dielectric sphere

We tested both FDTD and FEM programs with Rayleigh scattering test spheres. As an example, the 3D FDTD calculation is shown for polystyrene spheres (radius 40 nm and 150 nm, refractive index, $n = 1.56$) in Figure 5.2.1B, and the typical Rayleigh scattering cross section profile of $\sigma_s \propto \frac{1}{\lambda^4}$ is produced for the sphere that is small compared to the wavelength. As the sphere size approaches the size of the wavelength, there is significant interference between the light emanating from different locations on the particle (Figure 5.2.1 A), and Mie scattering is found. Figure 5.2.1 C shows the far-field calculation at wavelengths of 200 nm, 300 nm, and 800 nm for the polystyrene (radius = 150 nm) to show the interference.

Figure 5.2.1: Calculated spectra of the scattering for a polystyrene sphere ($n = 1.56$). (a) polystyrene diameter, $D = 300$ nm, (b) $D = 80$ nm. (c) Illustration of the far-field scattering amplitude for the $D = 300$ nm polystyrene sphere at different wavelengths. (C.1) Polystyrene sphere image. Far-field scattering at 200 nm (C.2), 300 nm (C.3), and 800 nm (C.4) wavelength. As the wavelengths approaches the particle size, there is interference between light emanating from different areas of the particle. White arrows indicate the directions of the main lobe of the far-field. Green, blue, red arrows are x, y, z axes. 3D FDTD simulation was used for the numerical calculation.

5.3.2 Far-field calculation for a free-standing truncated tetrahedron gold MNP in air

Figure 5.3.1 (A) shows the calculated extinction spectrum for a gold truncated tetrahedron MNP ($b = 20$ nm, $h = 117$ nm) using a 3D FDTD calculation. The free-standing tetrahedron shows a resonance peak position at 740 nm wavelength (red empty circle in Figure 5.3.1 A). This peak position is blue-shifted about 200 nm compared to

our experimental result, which is shown in Figure 4.3.1 in chapter 4. This large difference in peak position is due to the influence of the substrate in the experimental configuration. DDA calculations have previously shown that the influence of the substrate is crucial in obtaining the correct resonance peak position [13]. Those calculations showed that, as the MNP is embedded into a substrate from free standing to fully embedded in the substrate, the resonance peak position shifts to red. The influence of the substrate will be investigated further in section 5.3.4 below.

To calculate the local refractive index sensitivity of the particle, a 2 nm thick hexadecanethiol (HDT) layer ($\varepsilon = 2.1$) was applied to the gold MNP surface, which corresponds to the exposed surface of a gold UNSL MNP (Figure 5.3.1 B). The peak shift is 30 nm from 740 nm to 770 nm wavelength (blue filled circle in Figure 5.3.1 A). This calculation matches our experimental peak shift result as shown in Figure 4.5.2 in chapter 4, although the absolute positions are different due to the substrate influence. The particle size was $h = 117$ nm and $b = 20$ nm in the experiment.

XFDTD® allows only for an air environment in the numerical calculation, and FEMLAB® calculations with a bulk dielectric ambient are also inaccurate. Using the relative refractive index can address homogeneous environments. For half-spaces, such as for simulating the water-glass interface, disturbances arise, and therefore the glass medium is approximated in this thesis by a thin layer rather than the full space.

Figure 5.3.1 : 3D FDTD calculation for extinction spectra of a gold truncated tetrahedron particle with and without hexadecanethiol (HDT) surface modification on a gold MNP. (a) The plasmon resonance of a truncated gold tetrahedron particle is at 740 nm in air as in the free standing case (red empty circle and red fit curve). After HDT binding to the gold surface, the plasmon peak shifts to red to 770 nm (blue filled circle and blue fit curve). This corresponds to the 30 nm of the peak shift we found experimentally. (b) Illustration of the gold nanoparticle with a HDT layer used in the calculation. The particle bisector is $h = 117$ nm and thickness = 20 nm.

5.3.3 Near-field intensity distribution near the sharp features of non-spherical MNPs

FEMLAB and XFDTD simulation were used to study the near-field enhancement in 2D and 3D for the non-spherical gold MNPs. The 2D triangular shape corresponds to the bottom and the top of the truncated tetrahedron, and the plane wave propagates into the plane (Figure 5.4.1). The triangle size is $h = 117$ nm and the side length $a = 135$ nm (equilateral triangle). The resonance peak wavelength 740 nm (Figure 5.3.1) was used for the near-field polarization study.

As the polarization direction of the light is changed, the distribution of the near-field calculation, especially at the corners of the triangle, is changed (Figure 5.4.1 A and B). The field enhancement always exists along the polarization direction. This agrees

with reports of other numerical calculations [13, 22]. Similarly, in 3D the polarization direction also determines the location of the near-field enhancement on the non-spherical nanoparticle (Figure 5.4.1 C and D). Un-polarized light interaction with the triangle is the sum of these two polarized excitations, thus it must show high field enhancement at three corners (not shown here).

Figure 5.4.1: Near-field enhancement simulation with triangular MNPs, with the light propagating into the plane. (a) and (b) show 2D out-of-plane FEMLAB simulations at 740nm for the triangle surface with two different linear polarization directions of the incident light along the two different symmetry axes. (c) and (d) show 3D XFDTD simulations for the same polarized light excitations. Pairs (a) and (c) and (b) and (d) are in the same polarized light direction, respectively. Each near-field enhancement exists only in the polarization direction of the incident light. Red color in (a),(b),(c), and (d) indicates the maximum of E-near field..

The influence of sharp corners in the near-field and far-field was studied with 2D FEMLAB calculations. 2D FEMLAB allows far-field calculations only in the in-plane mode (propagation in the plane), but not in the out-of-plane mode (propagation into the plane) simulation. Therefore, in-plane simulations in 2D FEMLAB were used to investigate the far-field and the near-field distribution around the sharp corners in the triangle, although this is not the experimental situation. An equilateral gold triangle ($h = 117$ nm) was used to show the scattering spectra for the gold triangle, rounded triangle, and gold sphere with radius 50 nm (Figure 5.4.2). As the gold triangle with the in-plane resonance peak position at 560 nm (red line, (1)) becomes rounded, the peak position shifts to the blue at 540 nm (green line, (2)). For comparison, a gold sphere with

50 nm radius and equal cross-sectional area has the resonance peak position at 520 nm. The geometrical shape influence on the spectral position corresponds with others' experimental results [16] and DDA calculations [22]. DDA calculations showed that as the sharp edges of triangular prisms are snipped, the resonance peak shifts to the blue [13].

Figure 5.4.2 : Simulation of the influence of the shape on the scattering by gold MNPs. (1) Scattering by a gold triangle (bisector $h = 117$ nm, side length is $a = 135$ nm) with the resonance peak position at 560 nm (red curve). (2) As the gold triangle MNP becomes rounded, the peak position shifts to the blue to 540 nm (green curve). (3) For comparison, a gold sphere with 50 nm radius, which has the same cross-sectional area as the triangle has the resonance peak position at 520 nm (blue curve) The numerical calculation was done with a 2D FEMLAB simulation.

The near-field distribution corresponding for the spectrum analysis in Figure 5.4.2 is shown in Figure 5.4.3. The propagation direction of the incident light is in the x direction. The E fields exist only in the y direction (y -polarized). The resonance wavelengths were chosen to investigate the maximum near-field intensity. The maximum $|E|$ from the gold triangle is 5092 V/m at 560 nm wavelength (Figure 5.4.3 A). When the particle edges become rounded, the maximum near-field intensity drops to 2349 V/m at the resonance peak position of 540 nm (Figure 5.4.3 B).

The maximum near-field value from a 50 nm gold sphere is 935 V/m at 520 nm wavelength (Figure 5.4.3 C). The field around the triangle is enhanced by 544 % over the sphere, but the field from the slightly rounded triangle is reduced by 46 % from the snipped triangle. The $|E|$ of incoming E field is 376 V/m. Thus, it is clear that non-spherical MNPs have a much higher near-field intensity, which agrees with data shown by Schatz's group [34]. The maximum field intensity at the tip of the particle determined from a 2D FEMLAB in-plane calculation exists along the polarization direction, which is consistent with other reports [22, 34] and our simulations (Figure 5.4.1).

Figure 5.4.3: Illustration of the electric near-field enhancement $|E|$ at sharp and rounded edges. The maximum $|E|$ at the gold triangle of the same size as the sphere is 5092 V/m at 560 nm wavelength (a). The maximum field at the rounded triangle is 2349 V/m at 540 nm wavelength (b). The maximum field of a 50 nm radius gold sphere is 935 V/m at 520 nm wavelength (c). The field around the triangle is enhanced 544 % over the sphere, but the field from the slightly rounded triangle is reduced by 46 %. Wavelengths used for each simulation are at the resonance peak position. The $|E|$ of incoming E field is 376 V/m.

5.3.4 Substrate influence of the near-field intensity of non-spherical MNPs

NSL and UNSL MNPs are in close contact with a substrate, which influences the local field and possibly the sensitivity. Therefore understanding the near-field distribution around the corners and edges, the E-field enhancement and the relationship between the near-field and the far-field calculation is important. How the interaction with a substrate

close to MNPs influences the near-field distribution is also a very important aspect in understanding plasmonic sensors.

To investigate the near-field distribution in 2D in various geometrical settings, a cross-sectional study is useful. A 2D FEMLAB in-plane calculation was used, because the scattering calculation is only reliable in 2D FEMLAB in-plane mode. We simulated the near-field and far-field changes induced by a glass substrate, simulated as a 40 nm thick and 234 nm long slab at different particle positions relative to the substrate. Figure 5.5.1 shows the substrate influence on the scattering cross-section on a gold MNP with $h = 117$ nm. A free-standing Au tetrahedron cross-section has the resonance peak at 590 nm wavelength (Figure 5.5.1 (1)). This is blue-shifted from our 3D FDTD calculation result (Figure 5.3.1) presumably due to the restriction to 2D.

As the gold MNP approaches the glass substrate, the resonance peak position shifts to the red, in qualitative agreement with DDA calculations [13]. An UNSL-Au MNP has a red-shifted peak position at 640 nm compared to the free standing (Figure 5.5.1 (2)). a NSL-Au MNP at 645 nm (Figure 5.5.1 (3)), and a Au tetrahedron MNP which is flipped relative to the glass substrate (called "flipped NSL-Au") at 635 nm (Figure 5.5.1. (4)). Therefore, no matter how the gold MNP touches the glass substrate, the resonance peak positions of these particles are close.

The experimental resonance peak positions of Au UNSL and NSL MNPs show corresponding results (Figure 5.5.1 B). Au NSL MNPs ($h = 117$ nm, $b = 25$ nm) have a resonance peak position at 860 nm wavelength, while Au UNSL MNPs (bisector $h = 17$ nm, $b = 25$ nm) have a resonance peak position at 887 nm wavelength. The difference of 27 nm between the peak positions of UNSL-Au and NSL-Au is also relatively small. The difference in absolute peak positions for the measured data (Figure 5.5.1 B) and the 3D calculated data of a free-standing UNSL-Au MNP (Figure 5.3.1 A) is understood as

the substrate influence in the experiment, which causes the red-shifted resonance peaks. A 3D DDA calculation showed that the substrate can induce about 100 nm of red-shift [13], while our 2D FEMLAB in-plane calculation shows a 50 nm red shift.

Figure 5.5.1: Calculated scattering data and measured absorption data for the substrate influence on the extinction spectra for various gold MNP positions relative to the glass substrate. (A) (1) Au nanoparticle free-standing in air. The resonance peak position is at 590 nm (2) Au UNSL in air with the resonance peak position at 640 nm (3) Au NSL in air with the resonance peak position at 645 nm (4) Au flipped NSL in air with the resonance peak position at 635 nm. The particle thickness was 20 nm, the bisector of the bottom surface was 117 nm, and the bisector of the top surface was 103 nm. 2D FEMLAB in-plane calculation was used. (B) Measured absorption spectra for UNSL-fabricated Au and NSL-fabricated Au (bisector = 117 nm, thickness = 25 nm). UNSL-Au has a resonance peak positions at 887 nm wavelength and NSL-Au at 860 nm wavelength.

Although there is a small influence from the orientation of the MNP relative to the substrate in the far-field, this is not true in the near-field calculation. 2D FEMLAB in-plane simulations allow us to investigate the near-field of a UNSL-Au MNP in a cross-sectional view. The cross-section of a truncated tetrahedron is shown in Figure 5.5.2 and shows the maximum E-field at the near-field with various substrate positions. The

polarization of the E-field in Figure 5.5.2 corresponds to the polarization in Figure 5.4.1 B and D.

For the free-standing MNP, the maximum E-field intensity $|E|_{\max}$ is at the longest side with the sharper corners, which is the bottom face of the truncated tetrahedron (Figure 5.5.2 A). This is our sensing surface as the exposed surface of UNSL-fabricated MNP. The free-standing MNP has $|E|_{\max} = 6607$ V/m at 590 nm wavelength, which is the resonance peak position (Table 5.1 and Figure 5.5.1 A). For a UNSL-Au MNP, $|E|_{\max} = 4999$ V/m is located at the same geometrical position of the particle, but now at the air/glass interface (Figure 5.5.2 B). Interestingly, the smaller completely embedded side also has a higher field compared to the free-standing MNP. This is due to the field confinement at the interface and is not found in NSL-Au on the surface pointing away from the substrate. For NSL-Au MNPs, $|E|_{\max} = 8371$ V/m at 645 nm at the air/glass interface and also at the same geometrical position (Figure 5.5.2 C). When an NSL-Au MNP is flipped on the glass substrate, which is called "flipped NSL-Au" here, the position of $|E|_{\max}$ is changed to the smaller side, which is the top face of the truncated tetrahedron and in contact with the air/glass interface (Figure 5.5.2 D), thereby always staying close to the glass interface. $|E|_{\max}$ of the flipped NSL-Au is 6586 V/m at 635 nm wavelength.

This cross-sectional near-field analysis of the influence of the substrate provides valuable information. First, it shows that maximum $|E|_{\max}$ always exists on the sharp edges or corners at the resonance wavelength (Table 5.1 and Figure 5.5.2). Second, the $|E|_{\max}$ is always at the medium interface such as air/glass. Third, the location of $|E|_{\max}$ is not dependent on the incident wavelength. Every $|E|_{\max}$ value was calculated for the whole spectrum, and the location of $|E|_{\max}$ did not change (Table 5.1).

Figure 5.5.2: Substrate influence on the near-field distribution in cross-sectional view. (a) Free-standing Au pyramid in air at 590 nm wavelength. (b) UNSL-Au pyramid in the glass/ air interface at 640 nm wavelength. (c) NSL-Au pyramid at the glass/air interface at 645 nm wavelength. (d) Flipped NSL-Au pyramid at the glass/air interface at 635 nm wavelength. The pyramidal particle has a thickness of 20 nm, a bisector of the bottom surface of 117 nm, and a bisector of the top surface of 103 nm. Red color indicates the highest field intensity and blue color indicates the lowest field intensity.

Table 5.1 Maximum near field intensity, $ E _{\max}$, for various geometrical conditions. Measured at the same location on the MNP .				
Wavelength (nm)	Free standing (V/m)	UNSL (V/m)	NSL (V/m)	Flipped NSL (V/m)
590	6607	3573	5106	4512
630	5957	4924	8005	6539
635	5830	4976	8197	6585
640	5704	4999	8319	6579
645	5581	4996	8371	6526
650	5461	4969	8358	6434

Figure 5.5.3 shows the near-field enhancement at the substrate interface for a NSL-Au MNP and a UNSL-Au MNP in cross-sectional view. The enhanced fields are located at the tips and close to the interface between glass and air. To compare the near-field intensities for NSL and UNSL MNPs close to the edges, we analyzed the field 2 nm and 5 nm away from the surface of the MNP along a line indicated in Figure 5.5.3. The maximum near-field is 4950 V/m at 2 nm distance from the NSL-Au MNP, while the maximum near-field is 2792 V/m at 2 nm distance from the UNSL-Au MNP. The maximum near-field intensity 2 nm from the MNP is about 177 % higher for the NSL-Au MNP than for the UNSL-Au MNP (Figure 5.5.3 C). In Figure 5.5.3 C and D the solid line indicates the transition from air to glass for NSL, and the end of the UNSL particle, and both transitions have been aligned. As the distance from the particle is increased, the maximum near-field is reduced in both cases to 2600 V/m at 5 nm distance from the NSL-Au MNP, while the maximum near-field is reduced to 1800 V/m at 5 nm distance from the UNSL-Au MNP. The maximum near-field intensity at 5 nm distance from the MNP is still 144 % higher for the NSL-Au MNP than for the UNSL-Au MNP (Figure 5.5.3 D). The near-field decays faster laterally with distance from the edge of the NSL-Au MNP than for the UNSL-Au MNP at both 2nm and 5 nm distance from the MNP surface. Therefore, NSL-Au MNP has higher near-field than UNSL-Au MNP but the near-field in NSL-Au MNP drops more quickly. However, in reality this sharp edge is not easy to preserve in chemical solvents, which induce shape changes and reduce the sensitivity [7].

Figure 5.5.3: Cross-section of the near-field distribution at the air/glass interface for a NSL-Au MNP and a UNSL-Au MNP. (a) Near-field distribution of NSL-Au MNP with $|E|_{\max} = 8371$ V/m at the resonance wavelength of 645 nm. (b) Near-field distribution of UNSL-Au MNP with $|E|_{\max} = 4999$ V/m at the resonance wavelength of 640 nm. (c) Near-field intensity at 2 nm distance from both an UNSL (dotted line) and a NSL Au MNP (solid line), which shows a $|E|_{\max}$ about 177 % higher for NSL-Au than for UNSL-Au. (d) Near-field intensity at 5 nm distance from both an UNSL (dotted line) and a NSL Au MNP (solid line), which shows a $|E|_{\max}$ about 144 % higher for NSL-Au than for UNSL-Au. A solid line is shown to indicate the interface between air to glass in NSL-Au MNP and the end of the UNSL MNP.

5.4 CONCLUSIONS

Numerical calculations with FEM and FDTD simulations help us to understand what influences the LSPR in non-spherical MNPs. Our 3D FDTD calculation for the local refractive index sensitivity with an HDT layer supports our experimental results. The 3D FDTD and 2D FEM show that the polarization direction of the incoming light determines the polarization and near-field distribution on the non-spherical MNP. A 2D FEMLAB in-plane simulation was used to investigate the influence of the rounding of sharp features on LSPR peak position. As the sharp features become rounded, the LSPR peak position shifts to blue and $|E|_{\max}$ is also greatly reduced.

2D FEM were used for in-plane simulations, which easily display the geometrical influence on the LSPR, and provides explanations for the substrate influence. 2D FEMLAB in-plane cross-sectional investigations show that there is significant interaction between a substrate and the Au MNP. The substrate influences the $|E|_{\max}$ intensity and even the position of $|E|_{\max}$ on the MNP. $|E|_{\max}$ always exists on the substrate interface. Thus, $|E|_{\max}$ can be found at the interface with the substrate and the polarization direction. If there is no substrate, then $|E|_{\max}$ exists at the sharpest angles of the truncated tetrahedron MNPs.

A near-field analysis of the MNPs in cross-section shows that a NSL-Au MNP has higher near-field intensity than an UNSL-Au MNP due to the field confinement at the substrate. As the distance from the MNP is increased, the high near-field distribution around an NSL-Au MNP drops more quickly than for an UNSL-Au MNP. Therefore, these MNP geometrical aspects and the substrate contribution should be considered to optimize non-spherical MNP plasmonic sensors.

Chapter 6: Outlook

6.1 SUMMARY

Fabrication and characterization of non-spherical truncated tetrahedron MNP LSPR sensors have been explored in this dissertation. We achieved the following aims in this dissertation (i) develop a sensor that preserves the sharpness of the MNPs by partially embedding the particles in a substrate in order to achieve high sensitivity, (ii) optimize the sensitivity of the non-spherical MNPs by optimizing material and geometric parameters, (iii) and model the near- and far-fields around the MNPs with numerical simulations.

Aim (i), the investigation of non-spherical geometrical parameters, is achieved after developing a new fabrication technique, a carbon-based template-stripping method with NSL. This new fabrication technique allows us to combine various materials. In this dissertation, we used only SiO_2 , gold, and silver, but other materials have been applied. This method also allows us to control the non-symmetric geometry of the MNPs and so tailor the LSPR. We can optimize the sensitivity by controlling the particle thickness and bisector length. As the particle thickness is thinner, down to 17 nm, the sensitivity is drastically increased. We can also systematically increase the bisector size of the MNP, which induces an additional increase of sensitivity. Therefore, a thinner and longer MNP, one with highly elongated shape, has significantly improved bulk refractive index sensitivity, achieving nearly 100 nm of peak shift from air ($n = 1$) to water ($n = 1.33$). We achieved a higher sensitivity than any other MNP sensor except gold nanocrescents with our most sensitive UNSL-Au MNPs, which have 117 nm bisector length and nearly 300 nm/RIU sensitivity. This sensitivity could possibly be even more enhanced by

increasing the bisector size until reaching radiation damping. The sensitivities achieved for the bulk and surface refractive indexes are much higher than those achieved for gold NSL [1] and equal or higher than silver NSL [2, 3]. Further optimization of the shape by, for instance, inducing additional edges should allow further increases in sensitivity. The low sensitivity of silver UNSL is surprising and may be due to a higher importance of the oxidation at the silver surface in UNSL than in NSL.

Aim (ii) the characterization of an array type sensor for protein detection by changing the local refractive index, is shown by detecting an HDT monolayer on the nanopattern and by a multi-layer such as the sequential binding of the biotin-streptavidin pair. It was possible to detect HDT binding with a 30 nm shift of the peak to the red, and the binding of streptavidin to the biotinylated monolayer on the sensor from 100 nM solution. The gold MNP UNSL sensor detected the biotin binding event with 29 nm red shift and the streptavidin binding event on the biotin layer with 7 nm of red shift in air.

The specific aim (iii), the numerical simulation of the LSPR of a non-spherical MNP in near- and far-field, was studied by FDTD and FEM, and compared to experimental results. The numerical calculation, as expected, showed that the field enhancement is found at the sharp corners and edges. If the sharp corners are snipped, then the field intensity is significantly reduced and the far-field calculation showed that the resonance peak positions shift to the blue. These modeling tools also provided understanding of plasmonic behaviors for the more complicated MNP geometries. The maximum near-field intensity enhancement directly contributes to the far-field distribution which is measured with an UV-Vis spectrometer. The wavelength which induces the maximum near-field at a sharp corner is also the resonance peak position in the far-field calculation. There is substrate influence on the field enhancement due to the field confinement between the substrate and the particle. NSL-Au MNPs have a

significant substrate influence, which induces the higher near-field intensity due to the field confinement between the substrate and the sharp edges of the Au-MNP, while UNSL-Au MNPs have less near-field intensity because it has a different substrate position. However, in practical situation, NSL-Au MNPs lose the benefit from this field confinement, because of not being able to preserve sharpness in a chemical environment.

It is not shown whether or not there is a direct relationship between the enhanced near-field distribution and the increased sensitivity. This should be covered in future works.

6.2 FUTURE WORKS

There are still roads untaken in plasmonics, such as the tailoring of the light-metal material interaction by inducing more complicated shapes of the MNP. However, there are some limitations to systematically control MNP shapes and sizes in lithography, which restrict the understanding of non-conventional plasmonics in complicated geometrical situation. The new fabrication technique used in this dissertation may open a chance to implement non-conventional plasmonics [4-7] and possibly exploit the extraordinary transmission phenomenon [8] with a combination of different materials such as silver and gold combinations, or other metallic material mixtures [9-11], and systematically changing the geometric shapes and positions [12]. Thus, the non-conventional plasmonics should be explored with this new fabrication technique.

Changing more complicated sharp features in the MNP shape is expected to change sensitivity in different ways. Therefore, using not only the NSL method, but also other lithography methods such as Step and Flash Imprint Lithography (SFIL) [13] can provide different approaches to plasmonics. Combining the carbon-based template stripping method with SFIL will provide new types of non-spherical shaped arrays.

This thesis has explored immobilized MNPs so far, but a single non-spherical MNP can be useful as an image contrast agent. However, the sharp features of non-spherical MNPs are often easily rounded in solvents [14, 15]. Using the carbon-based template stripping method mentioned in this dissertation will provide opportunities to make free-standing non-spherical MNP with protection in chemical solvents.

FEMLAB 3.3a® and XFDTD® have some limitations in dielectric environment modeling. These tools are solid for modeling of air as a medium, but have difficulties with complex environments. This limits the study of the bulk refractive index sensitivity for the partially embedded non-spherical MNPs. A proper formulation of the boundary conditions in sections of the space should allow a more accurate description of the influence of the substrate and the enhancement of the local fields at interfaces. The direct relationship between the enhanced near-field and the increased sensitivity is not investigated thoroughly yet, due to the limitation to air as a medium in the modeling. Therefore, as soon as this limitation is resolved, the relationship between the enhanced near-field distribution and the increased sensitivity will be explored.

Vita

Bong-su Jung was born in Seoul, Korea on August 10th, 1972, as the eldest son of Woongchoong Jung and Eunsook Lee. After graduating from Junil High School in Jeon-Ju city, Korea in February 1991 he attended the department of Biomedical Engineering, Yonsei University, Korea. During college, from 1994 to 1996, he entered military service. He received the degree of Bachelor of Engineering from Yonsei University in February 1997. He joined a hardware research engineer team in the Research and Development Center at General Electric Medical Systems in Korea. While there from 1997 to 2001, he participated in designing an ultrasound diagnosis system, Logiq200 PRO and Logiq400 PRO. He received Best Engineer of the Year and Best Employee of the Year in 2000 and 2001, the most prestigious awards in the company. In September 2001, he entered the Biomedical Engineering department of the University of Texas at Austin, where he completed an M.S. degree in 2005 and a Ph.D. in September 2007. He is a member of the Materials Research Society, the American Institute of Chemical Engineers, Biomedical Engineering Society, and the Korean Society for Medical and Biological Engineering. In his free time he volunteers and lead a small bible study group for young adults at the Korean Baptist Church of Austin.
